A Model of Shadow Banking
Nicola Gennaioli, Andrei Shleifer and Robert Vishny

Third Draft, December 2011

Abstract

We present a model of shadow banking in which banks originate and trade loans, assemble them into diversified portfolios, and finance these portfolios externally with riskless debt. In this model: outside investor wealth drives the demand for riskless debt and indirectly for securitization, bank assets and leverage move together, banks become interconnected through markets, and banks increase their exposure to systematic risk as they reduce idiosyncratic risk through diversification. The shadow banking system is stable and welfare improving under rational expectations, but vulnerable to crises and liquidity dry-ups when investors ignore tail risks.

Gennaioli thanks the Barcelona GSE and the European Research Council for financial support.
1. Introduction

Several recent studies document the rise of the “shadow banking” system in the United States over the last decade (Coval et al. 2009a, Gorton and Metrick 2010, 2011, Poszar, Adrian, Ashcraft, and Boesky 2010, Shin 2009a). Shadow banking typically refers to financial activities occurring outside the regulated banking sector. In recent years, the most important such activities took the form of rapidly expanding provision of short term safe debt to financial intermediaries through money market funds and other sources outside of the regulated banking sector. Much of that debt was collateralized through the process called securitization, which involved origination and acquisition of loans by financial intermediaries, the assembly of these loans into diversified pools, and the tranching of these loans to manufacture safe pieces. While regulated banks played a key role in securitization and held large amounts of securitized assets, a high share of the ultimate financing of securitized assets was provided by the shadow banking system. The collapse of shadow banking in 2007-2008 has arguably played a critical role in undermining the regulated banking sector, and bringing about the financial crisis.

In this paper, we present a new model of shadow banking and securitization. In the model, a financial intermediary can originate or acquire both safe and risky loans, and can finance these loans both from its own resources and by issuing debt. The risky loans are subject both to institution-specific idiosyncratic risk and to aggregate risk. Critically, but in line with the actual experience (as documented, for example, by Bernanke et al. 2011), outside investors are only interested in riskless debt (they are assumed to be infinitely risk averse). When outside investors’ wealth is limited, demand for riskless debt is low, so intermediaries’ own wealth and returns from safe projects are sufficient to guarantee
whatever riskless debt they issue. However, at higher levels of investor wealth and demand for riskless debt, intermediaries cannot generate enough collateral with safe projects, and an intermediary’s own risky projects cannot serve as useful collateral for riskless debt because they are vulnerable to idiosyncratic risk. To meet the demand for riskless debt, intermediaries diversify their portfolios by buying and selling risky loans and eliminating idiosyncratic risk, similarly to Diamond (1984). Their assets in the form of loan portfolios, and their liabilities in the form of riskless debt issued to finance these portfolios, both grow together. Intermediaries essentially pursue a carry trade, in which they pledge the returns on their loan portfolio in the worst aggregate state of the world as collateral for riskless debt, and earn the upside in the better states of the world.

As intermediaries expand their balance sheets by buying risky projects, they increase systematic risk of their portfolios, and endogenously become interconnected by sharing each other’s risks. This is the critical new result of the paper: the very diversification that eliminates intermediary-specific risks by pooling loans so as to support the issuance of debt perceived to be riskless actually raises the exposure of these intermediaries to the tail aggregate risks. Still, under rational expectations, riskless debt is always repaid, and the system is very stable. The expansion of activity financed by the shadow banking system is Pareto-improving, as in standard models of risk sharing (Ross 1976, Allen and Gale 1994).

Things change dramatically when investors and intermediaries neglect tail risks, perhaps because they do not think about truly bad outcomes during quiet times. Gennaioli, Shleifer, and Vishny (GSV 2011) argue that the neglect of tail risk is critical to understanding aspects of the crisis. There is growing evidence that even sophisticated investors prior to the crisis did not appreciate the possibility of sharp declines in housing
prices (Gerardi et al. 2008), and did not have accurate models for pricing securitized debt, particularly Collateralized Debt Obligations (Jarrow et al. 2007, Coval et al. 2009a). GSV show that, with neglected risk, new financial products provide false substitutes for truly safe bonds, and as a consequence can reduce welfare.

In this paper, we further develop this argument by focusing more explicitly on how the shadow banking system offers insurance to investors. We model not only aggregate (as in GSV) but also idiosyncratic risk. By enabling the diversification of idiosyncratic risk, securitization promotes the expansion of balance sheets of the banks and increases financial links among them. Through these channels, the insurance against idiosyncratic risk interacts with the neglect of tail aggregate risks in creating extreme financial fragility. Gordon Brown (2010) refers to this phenomenon as “the diversification myth.”

In the range of parameter values corresponding to extensive securitization, investors neglecting downside risks believe that the payoffs on the collateral in the worst case scenario are higher than they actually are, and buy more debt thinking that it is riskless. The balance sheets of intermediaries expand further than they would under rational expectations. However, as intermediaries pool loans and diversify their idiosyncratic risk to support debt issuance, they increase their exposure to systematic risk. When they and investors realize that a worse state of the world than they had previously contemplated might occur, intermediaries face massive exposure to that downside risk, which they bear because they sold “riskless” bonds to investors. When securitization has proceeded far enough, systematic risk becomes systemic in the sense that massive exposure to macroeconomic risk causes all intermediaries to fail together. While harmless when market participants recognize all risks, the “diversification myth” becomes deadly when they do not.
The model describes the shadow banking system prior to the crisis, and many findings about it, even under the assumption of rational expectations. First, the model explains the critical role of rising demand for safe assets in driving the growth of the shadow banking system. Several studies have previously noted the roles of global imbalances (Caballero, Farhi, and Gourinchas 2008, Caballero 2009, Caballero and Krishnamurthy 2009) and of the demand for riskless debt (Krishnamurthy and Vissing-Jorgensen 2008, Bernanke, Bertaut, DeMarco, and Kamin 2011) prior to the financial crisis.

Second, the model explains the famous finding of Adrian and Shin (2010) that intermediary leverage and balance sheet expansion go together. In the model, as investor wealth grows, intermediaries accommodate the growing demand for riskless debt by expanding their assets, creating the correlation identified by Adrian and Shin.

Third, the model captures how the operation of the shadow banking system necessitates the retention of massive exposure to systematic risk by financial intermediaries, precisely as a byproduct of delivering riskless debt to investors. As idiosyncratic risk is diversified, systematic risk is concentrated. This critical feature of securitization was first stressed by Coval, Jurek, and Stafford (2009b), and explains the puzzle raised by Acharya and Richardson (eds., 2009) and Acharya, Schnabl and Suarez (2011) that banks retained a large fraction of aggregate risk on their balance sheets in the wake of the crisis.

Fourth, the model explains the growing interdependence between financial intermediaries even without the frequently-made assumption of complex networks of bilateral ties (Allen and Gale 2000, Shin 2009b, Allen, Babus and Carletti 2010). In our model, all the interdependence among intermediaries comes from competitive market trades.
Fifth, the model accounts for the growing body of evidence that financial institutions increase their risk-taking when interest rates are low (Greenwood and Hanson 2011, Maddaloni and Peydro 2011). In our model, risk taking is high in low interest rate environments because investor demand for riskless debt simultaneously drives down rates and increases the availability of capital to intermediaries.

In addition to these implications, our model delivers several features of the crisis under the neglected risk assumption. In particular, our model of securitization captures the fact that financial intermediaries lost money in the crisis on AAA-rated securities they held (Benmelech and Dlugosz 2009, Erel, Nadauld, and Stulz 2011). In our model, intermediaries pool and tranch projects to create collateral perceived to be completely safe, and then issue debt likewise perceived to be safe backed by this collateral and additional guarantees\(^2\). When a neglected bad state of the world is realized, the AAA-rated collateral turns out to be risky and falls in value, resulting in losses by intermediaries. To the extent that liquidity guarantees and other profits earned by the intermediaries do not suffice to pay off the debt they issue when the value of collateral falls, such debt becomes risky as well. The combination of excessive insurance and leverage precipitates the crisis.

In addition, the model exhibits extreme vulnerability of the financial system to news about the realization of neglected tail risks. This vulnerability arises from the sheer size of the shadow banking system, the unwillingness of investors to bear any risk, leaving it all to intermediaries, and the mechanics of securitization in increasing leverage and concentrating systematic risks.

\(^2\) An important reason why banks may have retained AAA-rated asset backed securities and used them as collateral rather than sold them off directly is the demand by outside investors such as money market funds for short term debt. We do not model this maturity transformation in this paper.
Finally, an extension of our basic model allows us to speak about liquidity dry ups during the crisis. There is a vast literature on the determinants of liquidity and its cyclicality (e.g., Acharya and Pedersen 2005). Here we show that securitization is also a contributing factor. When investors realize that debt they perceive to be riskless actually is not, they want to sell it. However, since even well performing intermediaries are hit by unexpected losses on their diversified pools, they might not have enough free resources to support the prices of this debt in the face of a selloff by outside investors, leading to a collapse of debt markets and growing risk premia (Shleifer and Vishny 1992, 2010, Brunnermeier 2009, Gorton and Metrick 2010, 2011, Stein 2011).

Our paper deals with several key aspects of securitization, but not all of them. We do not stress the maturity transformation and runs by short term creditors as triggers of the crisis (even though we discuss short term debt in Section 5). The run aspects of the crisis have been emphasized by several authors, including Shin (2009a), Brunnermeier (2009), and Gorton and Metrick (2010, 2011). In our view, the financial crisis has a lot to do with a massive and unanticipated shock to the assets of the financial intermediaries, and specifically assets used as collateral for short term debt. Some supporting evidence for this point of view is beginning to emerge (UBS shareholder report, Copeland et al. 2010, Krishnamurthy et al. 2011). We see the withdrawal of short term finance as largely a response to that shock and not a wholly separate cause of the crisis.

---

3For example, we do not model the idea that collateral in securitizations is ring fenced and thus available to creditors outside of bankruptcy proceedings, another feature designed to ensure the safety of debt (see Gorton and Souleles (2006) and Gorton and Metrick (2011b)). In our model, financial intermediaries use their own wealth and returns from risky projects (when positive) to satisfy debt claims, which makes those claims comparable to general debt. Alternatively, one can think of the intermediaries providing liquidity guarantees. At the same time, the use of AAA-rated ring-fenced collateral for short term debt demanded by money market funds is broadly consistent with our fundamental assumption that investors only want riskless debt.
The next section of the paper presents our basic model of the shadow banking system. Section 3 solves the model under rational expectations, and shows how shadow banking improves intertemporal trade, insurance opportunities, and welfare. In Section 4, we solve the model under the assumption of neglected risks, and show how false insurance provided by financial intermediaries when risks are ignored can misallocate risks. The very benefits of shadow banking obtained through diversification and leverage become the source of its demise. In Section 5, we add the opportunities for interim trading to the model, and examine the evolution of liquidity in the shadow banking system under neglected risks. We also briefly examine the role of short term debt. In Section 6 we compare our model to the two leading theories of securitization, namely adverse selection and regulatory arbitrage, and evaluate the three models in the context of the financial crisis. Section 7 concludes.

2. The Model

We build on the production model of GSV (2011), with three dates $t = 0, 1, 2$ and a measure one of investors who receive at $t = 0$ a perishable endowment $w$ and enjoy utility:

$$U = E_w[C_0 + \min_{\omega \in \Omega_1} C_{1,\omega} + \min_{\omega \in \Omega_2} C_{2,\omega}],$$

(1)

where $C_{t,\omega}$ is consumption at $t = 1, 2$ in state of nature $\omega \in \Omega_t$. Investors are infinitely risk averse in the sense that they value future consumption levels at their worst-case scenario\(^4\).

Investors save by buying financial claims from a measure one of risk neutral intermediaries, who are indifferent between consuming at $t=0,1,2$. Intermediaries receive an endowment $w_{int} < 1$ at $t = 0$, and use it - along with the funds raised from investors - to

\(^4\)In asset pricing terms, investors have a strong aversion to negative skewness in returns. Harvey and Siddique (2000) provide evidence on conditional skewness preference and asset pricing.
finance two activities H and L. Activity H is riskless: by investing at \( t = 0 \) an amount \( I_{H,j} \) in it, intermediary \( j \) obtains the sure amount \( R \cdot I_{H,j} \) at \( t = 2 \). Activity L is risky: by investing at \( t = 0 \) an amount \( I_{L,j} \) in it, at \( t = 2 \) intermediary \( j \) obtains the amount:

\[
f(I_{L,j}) = \begin{cases} AI_{L,j} & \text{with probability } \pi_{\omega} \\ 0 & \text{with probability } 1 - \pi_{\omega} \end{cases},
\]

in state \( \omega \in \Omega_2 \). The return on the risky activity is i.i.d. across intermediaries, and \( \pi_{\omega} \) captures the share of investments that “succeed” in \( \omega \). There are three final states \( \Omega_2 = \{ g, d, r \} \) such that \( \pi_g > \pi_d > \pi_r \). Here \( g \) captures a “growth” state where most investments succeed, \( d \) a less productive “downturn,” \( r \) an even less productive “recession.” At \( t = 0 \) it is known that state \( \omega \in \Omega_2 \) occurs with probability \( \varphi_\omega > 0 \), where \( \sum_\omega \varphi_\omega = 1 \). Unlike in GSV (2011), here intermediaries are subject to idiosyncratic, and not only aggregate, risk.

The expected return of H is not smaller than that of L, namely \( R \geq E_{\omega}(\pi_{\omega}) \cdot A \), so that intermediaries (weakly) prefer to invest in the safe activity to investing in the risky one. Riskless projects are however in limited unit supply, formally \( \int_{j} I_{H,j} dj \leq 1 \) and there are no “storage” opportunities. To expand investment beyond this limit, intermediaries must undertake lower-return risky projects. We can view investment projects in this model as mortgages, with riskier mortgages also offering lower expected returns.\(^5\) Figure 1 shows the decreasing marginal return to investment in the economy. Low return projects are riskier,

\(^5\) That is, activity L is a marginal and risky investment (e.g., subprime mortgages) that intermediaries wish to undertake only after better investment opportunities (e.g., prime mortgages) are exhausted. We can think of banks as having their own broadly diversified but limited portfolios yielding the return \( R \), as in Diamond (1984), which they can use to support safe debt without securitization. But once the potential of that portfolio to support safe debt is exhausted, banks need to find a way to use risky projects to support riskless debt. What matters for our results is not that the risky investment yields a lower average return than the safe one, but that the safe investment is in limited supply. This assumption ensures that after all safe returns are pledged to creditors, additional financing can only be raised via securitization.
both in the aggregate and at the level of the intermediary (the dashed lines capture the possible realizations of returns at the level of an intermediary).

Figure 1: Marginal Return to Investment

In a given aggregate state of the world, each intermediary faces an idiosyncratic risk on its projects (mortgages), perhaps because it is costly to fully diversify its investments. The intermediary can diversify its idiosyncratic (but not aggregate) risk by buying the projects issued by other intermediaries. We thus assume that an intermediary cannot diversify all idiosyncratic risk through its own projects; it must buy those of others. The available evidence on asset-backed commercial paper conduits indeed shows that such vehicles held a variety of securities of different kinds from different countries (Acharya and Schnabl 2010). Since the intermediary is risk neutral, however, it does not value diversification per se.

Intermediaries raise funds in two ways. First, they issue riskless debt claims promising a sure return \( r \geq 1 \) at \( t = 2 \). Riskless debt is a senior security that pledges the lowest realization of the payoff on an intermediary’s total assets. Because this debt is senior, it is the
last security to absorb losses, if any. Our focus on riskless debt captures investor demand for AAA rated securities as driven by regulation, taste for characteristics, and risk aversion.

The second way for intermediaries to raise funds is to “securitize” their projects (mortgages), which here refers to selling them at $t = 0$ in exchange for cash. The price received by an intermediary for selling one unit of investment at $t = 0$ is equal to $p_H$ for a riskless project $H$ and to $p_L$ for a risky project $L$. Intermediaries can also trade projects among themselves, which we show below boosts their debt capacity. In our model debt and securitization are complements, as the bank puts together a diversified portfolio of projects, tranches it, and pledges the safe portion of returns to raise riskless debt. Diversification allows the creation of AAA-rated collateral to raise AAA-rated debt. For now we only consider safe cash flows as collateral; we allow intermediaries to back debt with risky collateral in Section 5.2.

The timing of the model works as follows. At $t = 0$, the return on risky projects is not known and each intermediary $j$: i) raises $D_j$ units of riskless debt promising to repay $rD_j$ at $t = 2$ (the intermediary lends if $D_j < 0$), and ii) sells $S_{H,j}$ and $S_{L,j}$ units of riskless and risky projects, respectively. Using its own wealth $w_{\text{int}}$ and the resources raised, the intermediary: i) invests $I_{H,j}$ and $I_{L,j}$ units in the riskless and risky projects of its own, respectively, and ii) buys $T_{H,j}$ and $T_{L,j}$ units, respectively, of riskless and risky projects financed by other intermediaries. Each investor $i$ chooses how much riskless debt $D_i$ to issue (the investor lends if $D_i < 0$) and how many securitized projects $T_{H,i}$ and $T_{L,i}$ to buy. (In equilibrium, investors will buy riskless debt and not trade in projects, but at the moment we keep the framework general.) Markets for debt and for securitized projects clear at competitive prices $r, p_H$ and $p_L$.

At $t = 1$, intermediaries can raise new funds, securitized projects can be re-traded, and investors can re-optimize their consumption decisions. At $t = 2$, output from projects is
produced and distributed to intermediaries and investors. The world ends.

Crucially, at $t = 1$ everyone learns the return on intermediaries’ risky projects and the aggregate state $\omega$. Formally, in Equation (1) we have $\Omega_1 = \Omega_2 = \{g, d, r\}$. As a consequence, at $t = 1$ all market participants share the same preferences and the same reservation prices over assets. Thus, markets at $t = 1$ play no role. We can view this model as consisting only of two dates, $t = 0$ and $t = 2$. In the extension of Section 5, the $t = 1$ market plays a key role.

We simplify the equilibrium analysis by assuming:

**A.1** $\pi_d A < 1$,

which implies that under both rational expectations and local thinking intermediaries can only borrow a limited amount of funds. Our main results do not rely on this assumption. We examine the joint determination of leverage and securitization, as well as the forms of securitization, by first assuming rational expectations and then turning to neglected risks.

### 3. Equilibrium under rational expectations

If an intermediary $j$ adopts a borrowing, investment and securitization policy $(D_j, I_{H,j}, I_{L,j}, S_{H,j}, S_{L,j}, T_{H,j}, T_{L,j})$ at $t = 0$, its expected profit is the following sum of three components:

$$
[R (I_{H,j} + T_{H,j} - S_{H,j}) + p_H (S_{H,j} - T_{H,j})] + \\
+ [E_\omega (\pi_\omega) A (I_{L,j} - S_{L,j}) + E_\omega (\pi_\omega) A T_{L,j} + p_L (S_{L,j} - T_{L,j})] + \\
- D_j - I_{H,j} - I_{L,j} + w_{int} - rD_j.
$$

The term in the first square bracket is the return earned at $t = 2$ on the $I_{H,j}$ riskless projects that the intermediary has financed or purchased in the market (for net amount $T_{H,j} - S_{H,j}$), plus the revenue earned at $t = 0$ from the net sales of safe projects at unit price $p_H$. 

The term in the second square brackets captures the same payoff for risky projects, with the key difference that now the expected return $E_{\omega}(\pi_\omega) \cdot A \cdot (I_{L,j} - S_{L,j})$ of an intermediary’s own investments must be kept distinct from the return it earns on securitized risky projects bought in the market $E_{\omega}(\pi_\omega) \cdot A \cdot T_{L,j}$. From the standpoint of the risk neutral intermediary, $(I_{L,j} - S_{L,j})$ and $T_{L,j}$ are equally appealing investments, as they yield the same average return. The risk profiles of these investments are very different, however. The intermediary’s own investment $(I_{L,j} - S_{L,j})$ is subject to both aggregate and idiosyncratic risk: in state $\omega$ it yields $A$ with probability $\pi_\omega$ and 0 otherwise. In contrast, the securitized projects are subject only to aggregate risk, for risky projects are ex-ante identical and the intermediary buys a diversified portfolio of such projects. That is, the securitized holdings $T_{L,j}$ include part of each intermediary’s investment project, yielding a sure return of $\pi_\omega \cdot A$ in state $\omega$.

In this model, securitization and trading allow project “pooling,” and also insurance contracts (in which case the “pooler” is the insurance company). Pooling is irrelevant for riskless projects, which yield $R$ both with pooling and in isolation. In contrast, pooling of risky projects can allow intermediaries to reduce idiosyncratic risk in their balance sheets and risk averse investors to achieve better diversification in their portfolios. Our model allows us to investigate when pooling occurs and how intermediaries and investors exploit it.

The third and final piece of Equation (3) is the intermediary’s profit at $t = 0$ net of securities trading (i.e. the available funds minus investment costs), minus the payment of debt at $t = 2$. To ease notation, objective (3) excludes borrowing and trading in projects at $t = 1$. As we argued previously, these markets are irrelevant when $\omega$ is learned perfectly at $t = 1$. 

13
The intermediary takes prices \((r, p_H, p_L)\) as given and maximizes its expected profit in Equation (3) subject to the following constraints. First, at \(t = 0\) investment and net asset purchases must be financed by the intermediary’s own and borrowed funds, namely:

\[
I_{H,j} + I_{L,j} + p_H(T_{H,j} - S_{H,j}) + p_L(T_{L,j} - S_{L,j}) \leq w_{int} + D_j. \tag{4}
\]

Second, debt issuance at \(t = 0\) must be such that the intermediary is able to repay riskless debt in the worst possible state of its balance sheet. This implies that:

\[
rD_j \leq R(I_{H,j} + T_{H,j} - S_{H,j}) + \pi_r \cdot A \cdot T_{L,j}. \tag{5}
\]

The intermediary can pledge to the creditors: i) its return \(R(I_{H,j} + T_{H,j} - S_{H,j})\) from riskless projects, and ii) its holdings of securitized risky projects evaluated in the worst possible aggregate payoff \(\pi_r\), namely \(\pi_r \cdot A \cdot T_{L,j}\). The intermediary cannot pledge the non-securitized risky projects \((I_{L,j} - S_{L,j})\) as collateral for debt payments. Vulnerable to the idiosyncratic risk of yielding zero, these projects cannot support riskless debt.

The final constraints concern the feasibility of securitization:

\[
S_{H,j} \leq I_{H,j}, \quad S_{L,j} \leq I_{L,j}, \tag{6}
\]

which simply say that intermediaries cannot securitize more than they invest. Note that in (6) intermediaries do not re-securitize portions of the acquired pool \(T_{L,j}\). Since the pool is already diversified, there is no benefit from doing so.

At prices \((r, p_H, p_L)\) intermediaries maximize (3) subject to (4) – (6). A representative investor \(i\) maximizes utility in (1) subject to the constraint that consumption at different times and states is equal to \(C_{0,i} = w + D_i - p_H T_{H,i} - p_L T_{L,i}, C_{1,\omega,i} = 0, C_{2,\omega,i} = -rD_i + RT_{H,i} + \pi_{\omega} \cdot A \cdot T_{L,i}\), where \(D_i\) is the investors’ borrowing at \(t = 0\), while \(T_{H,i}\) and \(T_{L,i}\) are the investor’s \(t = 0\) purchases of riskless and risky projects, respectively.
We now study the equilibrium of the model, starting with the allocation prevailing at $t = 0$ and then moving to see what happens as agents learn $\omega$ at $t = 1$. We focus on symmetric equilibria where all agents of a given type (intermediary or investor) make the same choices. Consistent with our prior notation, then, index $j$ captures the actions of the representative intermediary while index $i$ captures those of the representative investor. Here we provide the basic intuition behind our results, detailed proofs are in the appendix.

### 3.1 Securitization and leverage at $t = 0$

As a preliminary observation, note that in equilibrium investors lend to intermediaries (not the other way around) and the return on riskless bonds must satisfy $r \geq 1$. Since investors and intermediaries have the same time preferences, lending can only occur for investment purposes and intermediaries are the ones who can access investment projects. Accordingly, since investors are indifferent between consuming at $t = 0, 1, 2$, the condition $r \geq 1$ guarantees that lending to intermediaries makes investors weakly better off than autarky.

The second useful observation is that the purchase of a riskless bond and of a securitized riskless project must yield the same return, namely:

$$\frac{R}{p_H} = r. \quad (7)$$

If (7) is violated, investors’ preferences as to whether to buy safe debt or a safe loan are the opposite of intermediaries’ preferences as to what to issue, so in equilibrium (7) must hold.

Third, and crucially, investors’ reservation price $p_{L,inv}$ for securitized risky assets (i.e. the highest price at which they are willing to buy them) is equal to:

$$p_{L,inv} = \pi_r A. \quad (8)$$
Infinitely risk averse investors value a pool of risky projects at its lowest possible payoff, which is the one obtained in a recession. This is of course below these projects’ average return \( \bar{E}_w(\pi_w) \cdot A \). These points imply that in any equilibrium the following property holds:

**Lemma 1** For any given investment profile \((I_{Hj}, I_{Lj})\), intermediaries are indifferent between securitizing and not securitizing riskless projects. When the riskless debt constraint (5) is slack, intermediaries are also indifferent between securitizing and not securitizing risky projects. When that constraint is binding, intermediaries strictly prefer to securitize at least some risky projects. In such equilibria, we have that \( S_{Lj} > 0 \) and risky projects are bought by intermediaries, not by investors, so that \( S_{Lj} = T_{Lj} \).

In our model, issuing riskless debt against the return of a riskless project is equivalent to selling that project to investors. Thus, securitization of riskless projects is irrelevant and riskless debt perfectly substitutes for it. We therefore focus on equilibria where \( S_{Hj} = 0 \).

Securitization of risky projects is initially irrelevant, but only until the point when the debt constraint (5) becomes binding. As intermediaries need to absorb more investor wealth to finance risky projects, they start selling them off and buying risky projects from other intermediaries. By diversifying idiosyncratic risk, such securitization creates acceptable collateral, relaxing the debt constraint (5). Indeed, the point of securitization in this model is to relax the collateral constraint. While risk averse investors are unwilling to lend anything against an individual risky project (as the latter’s return may be 0), they are willing to lend something against a pool of risky projects since such a pool eliminates idiosyncratic risk.

---

6 The presence of (negligible) inventory or production costs of securitization would reinforce this conclusion.
As a consequence, to obtain financing intermediaries (not investors) end up holding securitized pools of risky projects. This arrangement boosts leverage because now intermediaries can issue debt against the diversified pool of projects. As evident from Equation (5), by buying an extra unit of the pool intermediaries can increase debt repayment at most up to investors’ reservation price $p_{\text{L,inv}} = \pi_r \cdot A$ for that unit.

Besides boosting leverage, this arrangement enhances risk sharing. In fact, another way to expand financing would be for investors to buy a pool of risky projects on their own. However, as Lemma 1 shows, this is not the market solution, since risk neutral intermediaries are the efficient bearers of the pool’s aggregate risk and are thus willing to pay more than investors for the pool. Intermediaries are eager to hold a pool because, at a given interest rate is $r$, they keep the excess return $[E_{\omega}(\pi_{\omega})A - r]$ on the pool. When $E_{\omega}(\pi_{\omega})A > r$ intermediaries essentially invest in a carry trade: they borrow at the low safe interest rate from investors, but then take on risk to gain the upside of risky projects. With infinitely risk averse investors and risk neutral intermediaries, there are large gains from such trade.

In sum, securitization in our model is an instrument enabling intermediaries to boost leverage for financing risky projects. By pooling risky projects, intermediaries eliminate idiosyncratic risk. By pledging the senior tranche of the pool to investors, they raise leverage. Combined with liquidity guarantees from safe projects, the senior tranche of the diversified pool of projects is safe, and thus serves as acceptable collateral for riskless debt. The question then arises: when does securitization take place and what does this imply for leverage, interest rates, and investments? In particular, we would like to know whether greater leverage is associated with larger assets of the intermediaries, and greater aggregate risk. The appendix proves the following characterization result:
Proposition 1 If $E_\omega(\pi_\omega)\cdot A > 1$, there are two thresholds $w^*$ and $w^{**}$ ($w^{**} > w^*$) such that, in equilibrium, intermediaries issue $D_j = \min(w, w^{**})$ and the $t = 0$ allocation fullfills:

a) If $w \leq 1 - w_{int}$, investor wealth is so low that only the safe project is financed and securitization does not occur. Formally, $I_{H,j} = w_{int} + w$, $I_{L,j} = 0$, and $S_{L,j} = T_{L,j} = 0$. The equilibrium interest rate is $r = R$.

b) If $w \in (1-w_{int}, R/E_\omega(\pi_\omega)\cdot A]$, investor wealth is sufficiently high that some risky projects are also financed, but the return on safe investments is enough to repay all debt. As a consequence, securitization does not yet occur. Formally, $I_{H,j} = 1$, $I_{L,j} = w_{int} + w - 1$, and $S_{L,j} = T_{L,j} = 0$. The equilibrium interest rate is $r = E_\omega(\pi_\omega)\cdot A$.

c) If $w \in (R/E_\omega(\pi_\omega)\cdot A, w^*)$, investor wealth starts to be high enough that not only are some risky projects funded, but the safe return is insufficient to repay debt. Partial securitization emerges in the amount that allows intermediaries to just absorb all investor wealth. Formally, $I_{H,j} = 1$, $I_{L,j} = w_{int} + w - 1$, and $S_{L,j} = T_{L,j} \in (0, I_{L,j})$. The equilibrium interest rate is still $r = E_\omega(\pi_\omega)\cdot A$.

d) If $w > w^*$, then investor wealth is so high that many risky projects are funded and securitization is maximal. Formally, $I_{H,j} = 1$, $I_{L,j} = w_{int} + \min(w, w^{**}) - 1$, and $S_{L,j} = T_{L,j} = I_{L,j}$. To allow intermediaries to absorb all of investor wealth, the interest rate must fall below the (average) return $E_\omega(\pi_\omega)\cdot A$ and is a decreasing function $r(w)$ of investors’ wealth.

The details of the equilibrium, including the prices $p_H$ and $p_L$, are described in the proof (which also studies the case in which $E_\omega(\pi_\omega)\cdot A \leq 1$). In Figure 2, the thick dotted line depicts the average return on investment and the bold line shows the equilibrium interest rate.
Figure 2: Interest rate, wealth, and securitization

The interest rate, securitization and leverage are driven by the interaction between the supply of funds, as captured by investors’ wealth \( w \), and the demand for funds, as captured by the return of investment and by intermediaries’ ability to issue riskless debt in Equation (5).

When intermediaries are able to pay interest on the debt equal to the marginal return of investment, the equilibrium interest rate is given by that return, as in the standard neoclassical analysis. Indeed, if \( r \) fell below the marginal return on investment, intermediaries would wish to issue more debt than investors’ wealth, which cannot happen in equilibrium. This is what happens in case a), where investors’ wealth is so low that only riskless projects are financed, namely \( I_{H,j} = w + w_{int} \), in which case it is obvious that \( r = R \). But this is also true in case b), where investors’ wealth allows some risky projects to be undertaken (i.e. \( I_{H,j} = 1 \), \( I_{L,j} = w + w_{int} - 1 \)). Since investors’ wealth is so low that \( R \geq E_{\omega}(\pi_\omega) \cdot A \cdot w \), intermediaries can pay the full marginal return to investors out of safe cash flows. Thus, in cases a) and b) investors’ wealth is sufficiently low that riskless debt can be issued without securitization.
Matters are different when \( w > R/E_\omega(\pi_\omega) \cdot A \). Now investors’ wealth is so large that the return from the limited supply of safe projects is alone insufficient to pay off debt at the marginal rate of return on investment. As (5) illustrates, to expand borrowing intermediaries must now engage in at least some securitization. In case c), investors’ wealth is not too large, and intermediaries can absorb this wealth by securitizing only partially. Here the interest rate can rise to the marginal product of investment to ensure that intermediaries have no appetite for further expanding securitization and borrowing beyond \( w \). As a result, given that now \( r = E_\omega(\pi_\omega) \cdot A \) and \( D_j = w \). Equation (5) implicitly pins down securitization through the constraint:

\[ E_\omega(\pi_\omega) \cdot A \cdot w = R + \pi_r \cdot A \cdot S_{L,j}, \]  

in which we have replaced the equilibrium condition \( S_{L,j} = T_{L,j} \). Equation (9) holds until all projects are securitized, namely until \( S_{L,j} \leq I_{L,j} = w_{\text{int}} + w - 1 \). This is the case provided:

\[ w \leq w^* = \frac{R/A + \pi_r (w_{\text{int}} - 1)}{E_\omega(\pi_\omega) - \pi_r}, \]  

which highlights the role of intermediaries’ own wealth and of the safe project as buffers against project risk, supporting the intermediary’s ability to borrow. High intermediary wealth \( w_{\text{int}} \) reduces the outside financing needs of risky projects, while the safe return \( R \) creates a cushion for repaying riskless debt and financing risky projects when \( r < R \).

As investors’ wealth grows beyond \( w^* \), we are in case d). Now financing constraints become very tight and intermediaries fully securitize the risky projects financed, setting \( S_{L,j} = I_{L,j} \). In this case, the interest rate must fall below the marginal product of investment for the riskless debt constraint to be satisfied, i.e. \( r < E_\omega(\pi_\omega) \cdot A \). This is the range in which securitization effectively allows intermediaries to obtain – on each specific unit of the pool acquired – an excess return \([E_\omega(\pi_\omega) \cdot A - r]\) from the carry trade of financing risky projects.
with safe debt. At the equilibrium quantities of investment and securitization \( I_{L,j} = S_{L,j} = w_{int} \) + \( w - 1 \), Equation (5) determines the equilibrium interest rate as:

\[
r(w) = \frac{R + \pi, A(w_{int} + w - 1)}{w},
\]

which falls in investors’ wealth \( w \). As \( w \) increases, there is a spiral of increasing leverage, investment, securitization and decreasing interest rates. This process continues as \( w \) continues to grow up to the level \( w^{**} \) at which \( r(w^{**}) = 1 \). At this point \( r \) is at its lower bound of 1. Further increases in investors’ wealth beyond \( w^{**} \) cannot be absorbed by intermediaries. The spiral of leverage, securitization and falling interest rate has now stopped.

In sum, in our model securitization appears only when marginal, risky, projects are financed. It is not needed when only safe projects are financed. As investor wealth becomes so large that many risky projects must be financed, securitization combined with the pledging of AAA-rated securities and liquidity guarantees is used to accommodate growing leverage.

### 3.2 The outcome at \( t = 1, 2 \) after \( \omega \) is learned

Given the investment and securitization patterns \( (I_{H,j}, I_{L,j}, S_{L,j}) \) at \( t = 0 \), consider what happens after \( \omega \) is learned. We focus on the most interesting case where the debt constraint (5) is binding and securitization is positive. Since investors have lent under a riskless debt contract, at \( t = 2 \) they in aggregate receive – for any given \( \omega \) – the promised amount:

\[
rD_j = R \cdot I_{H,j} + \pi, A \cdot S_{L,j}.
\]

Intermediaries, on the other hand, efficiently bear the aggregate risk associated with \( \omega \), but they also bear the idiosyncratic risk created by their own risky project to the extent that they only partially securitized it. For any \( \omega \), at \( t = 1 \) there are two classes of intermediaries.
The first class consists of “successful” intermediaries, whose risky project pays out. In state $\omega$ there are by definition $\pi_\omega$ such intermediaries, and their $t = 2$ revenues are equal to:

$$RI_{H,j} + \pi_\omega \cdot A \cdot S_{L,j} + A \cdot (I_{L,j} - S_{L,j}).$$  \hspace{1cm} (13)

By subtracting (12) from (13), we find that, for these successful intermediaries, profits at $t = 2$ are equal to $(\pi_\omega - \pi_r) \cdot A \cdot S_{L,j} + A \cdot (I_{L,j} - S_{L,j})$. These profits accrue from the securitized pool if $\pi_\omega > \pi_r$ and from the non-securitized investments that pay out.

The second class consists of “unsuccessful” (and not fully diversified) intermediaries whose risky project has not paid out. The revenues of these $1 - \pi_\omega$ intermediaries are equal to:

$$RI_{H,j} + \pi_\omega \cdot A \cdot S_{L,j} + 0 \cdot (I_{L,j} - S_{L,j}).$$  \hspace{1cm} (14)

By subtracting (12) from (14), we find that, for these “unsuccessful” intermediaries, profits at $t = 2$ are equal to $(\pi_\omega - \pi_r) \cdot A \cdot S_{L,j}$. All these profits accrue from holding the upside of the securitized pool of assets.

When securitization is full ($S_{L,j} = I_{L,j}$), there is no distinction between successful and unsuccessful intermediaries. All intermediaries earn the same profit $(\pi_\omega - \pi_r) \cdot A \cdot I_{L,j}$ in (13) and (14). This observation will turn out to be critical to understanding the link between securitization and fragility.

From this analysis, we can draw the following lessons. When all market participants hold rational expectations, securitization is a welfare improving instrument that facilitates a better allocation of risks, boosting leverage and thus productive investment. Thanks to securitization, the extremely risk averse market participants, namely investors, shed all of their risks. The risk neutral market participants, namely intermediaries, are happy to bear all the residual risk to earn the extra return. As long as all investors understand the risks, the system is stable and there is no link between securitization and fragility. Full securitization
eliminates idiosyncratic risk and creates stability. Even when securitization is only partial, investors anticipate that some idiosyncratic risk will turn out badly, which reduces the ability of any individual intermediary to borrow, so that even ex-post unsuccessful intermediaries are able to repay their debt.

This analysis of the shadow banking system explains a range of empirical phenomena. It accounts for the role of the wealth of extremely risk averse investors, which comes from the global imbalances, or institutional demand, in driving the demand for securitization (e.g., Caballero et al. 2008, Krishnamurthy and Vissing Jorgensen 2008). It explains how leverage and assets of intermediaries grow together (Adrian and Shin 2010). It explains how, in equilibrium, intermediaries pursuing a carry trade take marginal risky projects when interest rates are low (Maddaloni and Peydro 2011). It explains how, through securitization, intermediaries become endogenously interconnected (Allen et al. 2010). Finally, it explains how the diversification of idiosyncratic risk through securitization is accompanied by the concentration of systematic risks on the books of financial intermediaries (Acharya, Schnabl, and Suarez 2011). Under rational expectations, however, all these developments are benign.

At the same time, it is clear from the organization of the shadow banking system that it is extremely vulnerable to unanticipated shocks. The enormous size of the shadow banking system when outside investor wealth is high, the extreme distaste of those investors for bearing any risk which consequently piles up these risks with intermediaries, and the role of securitization in increasing leverage and concentrating systematic risks, all render shadow banking vulnerable to shocks. When we add such shocks to the model in the form of neglected low probability tail risks, the system becomes fragile. Shadow banking provides illusory rather than true insurance to investors, and as such it massively misallocates risk.
4. The case of local thinking

We model local thinking by assuming, following Gennaioli and Shleifer (2010) and GSV (2011), that at $t = 0$ both investors and intermediaries only think about the two most likely states. Recall that recession is the least likely state (i.e. $\varphi_g > \varphi_d > \varphi_r$). This prior distribution reflects a period of economic prosperity. At $t = 0$ expectations are thus formed based on the restricted state space $\Omega^{LT} \equiv \{g, d\}$, covering only the possibilities of growth and downturn. Superscript LT denotes the information set and beliefs of a local thinker.

There is a superficial tension between our assumptions of infinite risk aversion of investors and their neglect of tail downside risk. Shouldn’t infinite risk aversion imply extreme alertness to precisely such risks? The answer, in our view, is no. First, one assumption concerns preferences and the other concerns beliefs, which are logically separate. Experimental evidence suggests that individuals sometimes overweight small probability events when those are salient, but other times ignore them when they do not come to mind (Kahneman and Tversky 1979, Bordalo et al. 2011). The evidence on the forecasts of housing prices (Gerardi et al. 2008) and on models used by rating agencies (Jarrow et al. 2007, Coval et al. 2009a) shows precisely that the events that ultimately occurred were too extreme to be even contemplated in advance. Second, investors’ misperception may have been reinforced by the fact that they bought AAA rated securities, so classified by rating agencies using quantitative models and historical data. The ratings intended to reassure infinitely risk-averse investors that these securities met their tastes.

Unlike in GSV (2011), market participants are fully aware that intermediaries are subject to the idiosyncratic risk of obtaining a zero payoff. The subtler failure of rationality here is that market participants neglect the aggregate risk that only as few as $\pi_r$
intermediaries may be successful. Given the technology of Equation (2), this neglect creates two problems. First, it induces over-optimism about the average return of an individual intermediary, i.e. $E^{LT}_{\omega} (\pi_\omega) \cdot A > E_{\omega}(\pi_\omega) \cdot A$. Second, it induces market participants to neglect the fact that an intermediary may be unsuccessful precisely in a state, a recession with aggregate payoff $\pi_r \cdot A$, in which many other intermediaries are also unsuccessful. This second effect plays some role in Section 4.2, but will be especially important in Section 5.

4.1 Securitization and leverage at $t = 0$ under local thinking

Since expectations are the only object that changes relative to the case with full rationality, the equilibrium as of $t = 0$ is isomorphic to the rational expectations equilibrium of Proposition 1, except that: i) the true expected return $E_{\omega}(\pi_\omega) \cdot A$ is replaced by the local thinker’s expected return $E^{LT}_{\omega} (\pi_\omega) \cdot A = E(\pi_\omega | \omega = g, d) \cdot A$ and ii) the worst-case contemplated scenario is now a downturn rather than a recession. Thus, when valuing different securities the local thinker fails to account for their exposure to the recession. This neglect of risk implies that the thresholds $w^*$ and $w^{**}$ of Proposition 1 are replaced by $w^{*,LT}$ and $w^{**,LT}$ and one can check that $w^{**,LT} > w^{**}$ while $w^{*,LT}$ may be above or below $w^*$. The equilibrium is characterized by Proposition 2.

**Proposition 2** In equilibrium under local thinking, for any given level of investors’ wealth $w$: 

1) The interest rate is weakly higher than under rational expectations, i.e. $r^{LT} \geq r$.

2) Debt (and thus investment) is weakly higher than under rational expectations, i.e. $D^{LT} \geq D$.

3) Securitization arises for lower levels of wealth $w$ than under rational expectations, and for $w$ sufficiently large is higher than under rational expectations, i.e. $S_{LT}^{LT} \geq S_L$. 

25
To see the above results, note that the debt constraint under local thinking becomes:

\[ r D_j^{\text{LT}} \leq R \cdot I_{H,j}^{\text{LT}} + \pi_d \cdot A \cdot S_j^{\text{LT},L}. \]  

(15)

Under rational expectations, the corresponding expression was \( r D_j \leq R \cdot I_{H,j} + \pi_r \cdot A \cdot S_j^{L}. \) The shadow value of securitization is higher under local thinking: an extra securitized project expands leverage by \( \pi_d \cdot A \) under local thinking but only by \( \pi_r \cdot A \) under rational expectations. The insurance mechanism provided by securitization is believed to be very effective by local thinkers because in the worst-case scenario they consider a sizeable share (\( \pi_d \)) of the pooled projects succeed. This is not so under rational expectations, where only \( \pi_r \) of the projects are expected to succeed for sure.

This property implies that local thinking tends to boost the amount of debt repayment that can be sustained by securitization, but it does not say whether this boost will trigger an upward adjustment in the interest rate \( r \) or in the amount of leverage \( D^{\text{LT}} \) and investment \( I^{\text{LT}} \). Figure 3 graphically addresses this question for the case where \( w^{*,\text{LT}} < w^* \).

Figure 3: The interest rate under local thinking

---

When \( w^{*,\text{LT}} < w^* \) securitization is higher under local thinking, namely \( S_j^{\text{LT},L} \geq S_j^{L} \) for all \( w \). When instead \( w^{*,\text{LT}} > w^* \) there might be an intermediate wealth range where securitization is higher under rational expectations. The intuition is that, precisely because under rational expectations the shadow value of securitization is lower, intermediaries may need to use more of it to absorb investors’ wealth.
The bold and dashed lines plot the equilibrium interest rate under local thinking and rational expectations, respectively. The lines differ in the range when risky projects are undertaken, as local thinking intermediaries believe the return of these projects to be higher than under rational expectations. This boosts the interest rate to \( r_{\text{LT}}(\pi_{t0}) \cdot A \) and tightens debt constraints, forcing intermediaries to securitize starting at lower wealth levels and more extensively (indeed, \( R/E_{t0}(\pi_{t0}) \cdot A < R/E_{t0}(\pi_{t0}) \cdot A \)). As long as \( w \leq w^{**} \), intermediaries absorb all of investors’ wealth under both rational expectations and local thinking, so investment is the same in two cases (i.e., \( I_t = I_{\text{LT}} = w + w_{int} - 1 \)). In this range, the greater pace of securitization prevailing under local thinking just reflects a rat race among intermediaries that results in a higher interest rate, not in higher investment. As we will see, this implies that over some range, securitization creates fragility without an ex-ante benefit of greater investment.

In the range \( w \geq w^{**} \), local thinking fosters not only securitization, but also leverage and investment beyond the level prevailing under rational expectations. As investors’ wealth becomes very high, the interest rate must fall in order for intermediaries to absorb that wealth, but relatively less so under local thinking. Until wealth reaches \( w^{**.,\text{LT}} \), the shadow value of securitization under local thinking allows intermediaries to absorb more wealth from investors and to pay them a higher interest rate than under rational expectations. For \( w > w^{**.,\text{LT}} \), the interest rate under local thinking reaches its minimum of 1 and no more investor wealth can be absorbed. Now the only difference with rational expectations is reflected in the amount of leverage, which is higher under local thinking.

In sum, at \( t = 0 \) local thinking boosts the use of securitization relative to rational expectations, resulting either in a higher interest rate only (for \( w \leq w^{**} \)), or in higher
borrowing and interest rate (for $w^* < w < w^{**LT}$), or in higher borrowing only (for $w \geq w^{**LT}$). Similar effects are at play when $w^{**LT} > w^*$. We now consider the implications of this feature for the reaction of markets to news at $t = 1$.

4.2 Securitization and fragility at $t = 1$ under local thinking

Consider the investment and securitization profile $(I_{H,j}^{LT}, I_{L,j}^{LT}, S_{L,j}^{LT})$. If the state is growth or downturn, idiosyncratic shocks affect the profit of specific intermediaries, but riskless projects and securitized assets provide intermediaries with enough resources to repay their debt at $t = 2$. When the realized $\omega$ is in the support of the states considered by the local thinker, the outcome is qualitatively similar to that arising under rational expectations.

Matters change drastically in a recession. Now intermediaries realize that at $t = 2$ they may not have enough resources to repay their debt, thereby precipitating a default. To see how this possibility arises, consider the debt constraint of Equation (15). Since by Lemma 1 securitization is used when this constraint is binding, in any equilibrium with positive securitization the intermediary at $t = 0$ commits to repay at $t = 2$ the amount:

$$r^{LT}D^{LT} = R \cdot I_{H,j}^{LT} + \pi_d \cdot A \cdot S_{L,j}^{LT}.$$  \hfill (16)

Consider now the ability of different intermediaries to repay this debt. The measure $(1 - \pi_r)$ of unsuccessful intermediaries learns that their $t = 2$ operating profits are equal to:

$$R \cdot I_{H,j}^{LT} + \pi_r \cdot A \cdot S_{L,j}^{LT} + 0( I_{L,j}^{LT} - S_{L,j}^{LT} ).$$  \hfill (17)

By subtracting Equation (16) from (17), we see that unsuccessful intermediaries default at $t = 2$ because their operating profits are below the face value of debt by the amount $(\pi_d - \pi_r) \cdot A \cdot S_{L,j}^{LT} > 0$. The neglect of the risk of a recession plays a key role here: even though
intermediaries try to keep their debt safe by insuring against idiosyncratic risk, the fact that the securitized pool performs worse than expected by \((\pi_d - \pi_r)\) reveals that debt is risky and triggers a default. This problem arises because the local thinker neglects the possibility that an adverse idiosyncratic shock, against which the intermediary is insured, occurs precisely in a recession state when many other intermediaries are experiencing the same shock.

The measure \(\pi_r\) of successful intermediaries learns that their \(i = 2\) profits are equal to:

\[
R \cdot I_{L,j}^{LT} + \pi_r \cdot A \cdot S_{L,j}^{LT} + A \cdot (I_{L,j}^{LT} - S_{L,j}^{LT}).
\]  

(18)

By subtracting Equation (16) from (18), we see that successful intermediaries may or may not be able to repay their debt. In particular, Equation (18) is higher than (16) and thus successful intermediaries are solvent if and only if:

\[
\frac{I_{L,j}^{LT}}{S_{L,j}^{LT}} > 1 + (\pi_d - \pi_r).
\]  

(19)

This is a key equation. It says that for successful intermediaries not to default, the fraction of risky investment that is non-securitized must be sufficiently high relative to the cash flow shortfall resulting from their neglect of aggregate downside risk. If securitization is close enough to 0, condition (19) is satisfied and successful intermediaries repay their debt. In this case, after the unexpected recession occurs, a share \(1 - \pi_r\) of intermediaries defaults but a (potentially high) share \(\pi_r\) of intermediaries does not. If instead securitization is close to full \((S_{L,j}^{LT} \approx I_{L,j}^{LT})\), even successful intermediaries default. In this case, all intermediaries default!

When securitization is full, with probability \(\phi_g\), intermediaries get a true bonanza payoff; when their luck turns sour, with probability \(\phi_r\), they get a fouled carry trade and financial distress. Interestingly, Equation (19) reveals that financial fragility results from the
combination of the neglect of risks and high investor wealth through the volume of securitization $S_{L,j}^{LT}$. Even if the neglect of risk is small, formally $\pi_d \simeq \pi_r$, the financial system can collapse when investor wealth is so large that securitization is massive.

Somewhat paradoxically, the more intermediaries insure against idiosyncratic risk, the more they become exposed to unexpected and adverse aggregate shocks. The problem is that securitization does not only dampen the fluctuations in intermediaries’ balance sheets, but also allows them to take on more leverage. It is precisely this boost in leverage financing carry trades that renders intermediaries fragile. The combination of insurance and leverage is problematic because it creates a large correlation among the intermediaries’ response to neglected risks, de facto transforming riskless debt claims into catastrophe bonds, as noted by Coval et al. (2009b). This last point can be readily seen in the previous formalism: when condition (19) is not met, conditional on the realization of the unexpected state, a non-securitized (risky) debt claim defaults with probability $1 - \pi_r$, whereas an allegedly safe fully securitized debt claim defaults with probability 1!

By endogenizing leverage and securitization, our model allows us to determine when condition (19) is met and when it is not. The appendix proves the following result:

**Corollary 1** If $E_\omega(\pi_\omega)A > 1$, then there is a threshold $w \in (R/E^{LT}_{\pi_\omega}(\pi_\omega) \cdot A, w^{*LT})$ such that when a recession occurs, for $w \leq R/E^{LT}_{\pi_\omega}(\pi_\omega) \cdot A$ no intermediary defaults, for $w \in (R/E^{LT}_{\pi_\omega}(\pi_\omega) \cdot A, w)$ only $1 - \pi$, intermediaries default, and for $w > w$ all intermediaries default.

This result highlights the role of investors’ wealth, via the interest rate, in shaping financial fragility. When investors’ wealth is low, borrowing is limited. Intermediaries’
wealth $w_{int}$ is thus sufficient to sustain riskless borrowing, providing an effective buffer against unexpected shocks. As investors’ wealth rises, intermediaries’ wealth becomes too small to buffer against shocks. To sustain further borrowing, intermediaries must reduce balance sheet risk by securitizing some of their investments. When securitization is moderate, the unsuccessful intermediaries become vulnerable to unexpected aggregate shocks but the successful ones are still able to repay from the income generated by their own projects. When investors’ wealth becomes very high and the interest rate very low, intermediaries boost leverage by maxing out securitization. Now all intermediaries are equally unprepared to withstand the aggregate shock. Here securitization spreads unexpected aggregate shocks across all intermediaries, leading all of them to default. Systematic risk becomes systemic.

The analysis links several aspects of the financial crisis that were previously noted but not seen as related. We have already noted that, even under rational expectations, our model explains the role of the world savings glut in driving securitization, the cyclical comovement of bank assets and leverage, procyclical risk-taking by banks, increasing bank interdependence, and the concentration of aggregate risks on bank balance sheets in securitization. In our model, a high level of investor wealth leads to expanded securitization, growing leverage, growing assets of the intermediary sector, lower interest rates, and increased bank risk taking. Under the neglected risk assumption, the model yields additional implications. Most importantly, it shows that the system that is highly stable under rational expectations becomes extremely fragile and sensitive to tail risks because securitization entails growing bank interdependence. It also delivers the important prediction that securities perceived to be completely safe (AAA-rated) and used by banks as collateral for raising safe
outside debt suffer losses when tail risks are realized. Bank losses in a crisis come precisely from these AAA-rated securities created by tranching diversified portfolios of projects (Benmelech and Dlugosz 2009). In section 5, we show how an extension of the model also explains liquidity dryups in a crisis.

The source of fragility is the neglect of aggregate risk. Unlike in the case of rational expectations, where securitization allows an appropriate increase in leverage and investment, when market participants are local thinkers, securitization sustains excessive insurance and thus excessive leverage, which renders the economy very sensitive to unexpected adverse aggregate shocks. In the current model, excess securitization benefits intermediaries (who are able to exploit more profitable carry trades), but hurts investors by inducing them to over-lend and by exposing them to unexpected aggregate shocks. Since risk averse investors are inefficient bearers of this risk, excess securitization leads to a net social loss.

There is an alternative, but closely related, interpretation of the model. According to this view, securitization works through the creation of a standardized liquid market in whatever assets investors perceive to be safe (e.g., AAA-rated MBS). All the intermediaries borrow against these “safe” assets and probably even tilt their carry trades toward these assets because they are easier to lever up. The net result is that any investor misperception of risks results in massive investment in and borrowing against this “safe” asset class, creating a situation in which all intermediaries are vulnerable to the same sectoral risk. The high correlation of defaults across the intermediaries in the bad state results from loading up on exposure to this neglected risk. In our model it is diversification (and tradability, see Section 5) that creates the false perception of absolute safety and the high correlation of defaults, but the mechanism is potentially more general.
In the current model, agents learn about the neglected risk at \( t = 1 \) but fragility and losses are realized at \( t = 2 \), when defaults occur. In reality, in contrast, when bad news hit we often observe asset trading, price drops, and spikes in risk premia. The next section presents a modification of our basic setup where all of these features naturally emerge. Many other theories account for liquidity dry ups and spikes in risk premia, but our goal here is to show that securitization importantly contributes to their occurrence.\(^8\)

5. Securitization and leverage under slow arrival of information

We modify two assumptions from the previous setup. First, we assume that a fraction of risky projects pays off its return \( A \) at \( t = 1 \) rather than at \( t = 2 \). At \( t = 0 \), it is not known which projects pay out early. A project not repaying early need not be unsuccessful, since some successful project pay out late (e.g., restructured mortgages). The second departure from the previous setup is that the fraction of early-paying projects is partially informative about \( \omega \), perhaps because it acts as a signal of aggregate output.

Formally, we assume that at \( t = 1 \) either state \( h \) or \( l \) is realized. In state \( h \), a share \( q_h \) of intermediaries obtains \( A \) on their risky projects at \( t = 1 \), while the remaining \( 1 - q_h \) intermediaries must wait until \( t = 2 \) for their return to realize. In state \( l \), a share \( q_l < q_h \) of intermediaries receive \( A \) on their risky projects while the remaining \( 1 - q_l \) must wait until \( t = 2 \) for their return to realize. As a result, \( \Omega_1 = \{l,h\} \) and \( \Omega_2 = \{g,d,r\} \). The share of projects paying out “early” is informative about the aggregate state: the probability that any “late” project is successful at \( t = 2 \) is higher in state \( h \) than in state \( l \). We formalize this notion by

\(^8\) Our model has some of the same flavor as Geanakoplos (2009), especially in so far as he emphasizes the importance of pessimists financing the asset purchases of optimists with safe debt. Our approach differs from his in its focus on departures from rational expectations as opposed to differences of beliefs and in its focus on the welfare impact of securitization.
assuming that the unfolding of events is captured by the following event tree (which is chosen to nest the distribution of final states previously considered):

![Event Tree Diagram]

**Figure 4: Information tree**

In Figure 4, the nodes at $t = 1$ report the share of successful intermediaries at $t = 1$, while the nodes at $t = 2$ report the total share of successful intermediaries (at $t = 1$ and $t = 2$). The numbers in the branches capture the probabilities of moving up or down at a given node.

The aggregate state that we previously called “growth” here consists of a streak of good news, “downturn” consists of a mix of good and bad news, and “recession” is a streak of bad news. As of $t = 1$, state $h$ is good news, but it remains uncertain whether the overall state is $\pi_g$ or $\pi_d$, while state $l$ is bad news but it remains uncertain whether the overall state is $\pi_d$ or $\pi_r$.

Besides their informational content, the key implication of the presence of early projects is that intermediaries may use the portion of early returns that was not pledged to creditors to buy back some debt claims in secondary markets at $t = 1$. This second effect becomes critical in shaping changes in market liquidity when at $t = 1$ investors realize the presence of neglected risks.
At a more technical level, the presence of “early” projects also implies that some debt repayment must occur at $t = 1$ when the early projects in securitized holdings yield $q_o \cdot A \cdot S_{L,j}^{LT}$ (recall that there is no storage). This arrangement can be described as a long term fully safe debt contract promising one coupon at $t = 1$ and another at $t = 2$.\(^9\) We stress that, consistent with our prior assumption, debt continues to be fully riskless (within the states of the world that come to mind). To simplify the analysis, but with no consequence for our key results, we also assume a two tiered seniority structure within riskless debt. The most senior riskless debt is pledged up to the safe return $RI_{H,j}^{LT}$ and gets repaid at $t = 2$, while the less senior riskless debt is pledged the lowest return on the pool of securitized assets $\pi_d S_{L,j}^{LT}$. This second class of riskless debt gets part of its repayment at $t = 1$ and part at $t = 2$. The only role of this assumption is to simplify the working of secondary markets at $t = 1$, effectively turning them into markets where securitized pools are re-traded.

5.1 Securitization, Liquidity and Financial Fragility

To study the model, we focus on the case of local thinking. Consistent with the previous analysis, we model local thinking by assuming that at $t = 0$ agents only think about the two most likely paths in the tree. Under the assumption $\phi_d > \phi/(\phi_g + \phi_r)$, which we impose throughout, the most likely paths are growth and downturn, so that at $t = 0$ local thinkers prune the lower branch of the tree, considering only the upper one:

\(^9\) The same effects can be obtained by having short term debt rolled over at $t = 1$. We stick to long term debt for consistency with our previous analysis. An alternative is to have all projects pay out at $t = 2$ but to have some revealed to be successful at $t = 1$. In this case, intermediaries revealed to be successful at $t = 1$ could issue safe debt at this date to purchase claims in secondary markets. This alternative formulation would yield similar results to the current one, but requires a more cumbersome characterization of the market equilibrium at $t = 1$. 
Figure 5: The local thinker’s information tree

Upon observing the neglected state $q_l$ at $t = 1$, the only possible paths lead to a downturn or a recession. Market participants realize that they are in the lower branch of the tree, and take the previously neglected risk of a recession into account.

Consider the optimal policy of intermediaries at $t = 0$. Given the event tree in Figure 5, the investment-financing policies of intermediaries are isomorphic to those described in Section 4.1 under local thinking and full revelation of information. First, since investors are indifferent between consuming at different dates, at $t = 0$ they do not care about the timing of returns and lend the same amount they lent when they fully learned $\omega$ at $t = 1$ and consumed only at $t = 2$. The only technical difference is that now Figure 5 implies that the local thinker’s expected return is equal to $E_{\omega}(\pi_\omega|t=0) = \left[(\varphi_g + \varphi_r)\pi_g + \varphi_d\pi_d\right] A$, which differs from the average return expected by the local thinker in the static setup of Section 3.

Second, at any investment-securitization profile $(I_{LT_{H,j}}, I_{LT_{L,j}}, S_{LT_{L,j}})$, the supply of riskless bonds by intermediaries at $t = 0$ is unaffected by either of our new assumptions: the presence of “early” projects or by partial learning. The maximum amount of riskless cash flow that intermediaries can pledge is equal to the safe return $R \cdot I_{LT_{H,j}}$ plus the early return from securitization $q_h \cdot A \cdot S_{LT_{L,j}}$, plus the “late” return from securitization $(\pi_d - q_h)A \cdot S_{LT_{L,j}}$ valued at the
worst state investors are thinking about. The riskless debt constraint faced by intermediaries at $t = 0$ is thus given by:

$$rD_j \leq R \cdot I_{HL,j}^{LT} + \pi_d A \cdot S_{LT,j}^{LT},$$

(20)

which is identical to Equation (15) prevailing under full information revelation. Once again, the form of the debt constraint (20) is due to the fact that we focus on riskless debt. Section 5.2 however shows that, under the assumption of slow information arrival, intermediaries may boost debt capacity by issuing risky debt.

Although early projects and slow information arrival do not change the results of Proposition 2 concerning the $t = 0$ equilibrium prevailing under local thinking, this is not so outside of normal times, in the unexpected aggregate state $q_l$ at $t = 1$. Now matters become very different. If at $t = 1$ market participants observe an unexpectedly low share $q_l$ of “early” projects, they realize that they are in the lower branch of the tree in Figure 4, which they had previously neglected.

As in the local thinking analysis of Section 4.2, investors now suddenly realize that what can be pledged in the worst state of nature by each intermediary from its own securitized holdings $S_{LT,j}^{LT}$ drops by the amount $(\pi_d - \pi_r)A \cdot S_{LT,j}^{LT}$. Most important, since at $t = 1$ there is residual uncertainty as to whether the final state is recession or downturn, there is residual risk in the claim held by investors. Since investors are not efficient bearers of this risk, there is a rationale for them to sell their (now risky) debt claim to risk neutral intermediaries. This is particularly problematic for “late” intermediaries whose risky project has not paid at $t = 1$, as the debt they issued against securitized pools now faces a severe risk

---

10 This reduction in investors’ own valuation of debt is due to an unanticipated drop in $t = 1$ repayment of $(q_h - q_l)A S_{LT,j}^{LT}$ plus a drop in $t = 2$ repayment of $(\pi_d - \pi_r - q_h + q_l)A S_{LT,j}^{LT}$. 

of default (the fact that only securitized debt claims are subject to default risk is due to our simplifying assumption of a two tiered debt seniority structure).

To see this, consider the securitized assets of a generic late intermediary. The investors that had been pledged up to $\pi_d \cdot A \cdot S_{LT}^{L,j}$ by the intermediary from these assets, upon observing $q_l$ effectively become owners of the cash flow generated by these assets and value it at the worst case value $\pi_r \cdot A \cdot S_{LT}^{L,j}$. On the demand side, an early intermediary having some spare liquidity at $t = 1$ has a higher reservation price $E(\pi_{\omega} | \omega = l) \cdot A \cdot S_{LT}^{L,j} > \pi_r \cdot A \cdot S_{LT}^{L,j}$ for the cash flow generated by the securitized assets of a late intermediary. To reiterate, there are gains for risk averse investors to sell their risky debt claims on late intermediaries to the risk neutral early intermediaries having some spare liquidity at $t = 1$, and for these intermediaries to purchase this debt. Notwithstanding these gains, the key question is what volume of trade can be sustained at $t = 1$ by the wealth of the $q_l$ early intermediaries confronted with the supply of the securitized (now risky) debt of the remaining $(1 - q_l)$ of late intermediaries.

To determine the equilibrium, denote by $V_1$ the total market value of this now risky debt at $t = 1$. Even if $V_1$ is below their valuation, early intermediaries are only able to buy debt to the extent that they have enough resources available. At $t = 1$, the total resources available to early intermediaries to buy debt claims in secondary markets are equal to

$$q_l[A \cdot (I_{LT}^{L,j} - S_{LT}^{L,j}) - (\pi_d - \pi_r)A \cdot S_{LT}^{L,j}],$$

which consists of the payoff from “early” projects that were not securitized (and thus not pledged to creditors) minus the unexpected drop in the lowest value of the securitized assets.

\[11\] For simplicity we are assume that trading occurs before the $t = 1$ debt repayment is made, so that the value of the debt includes the coupon $q_l A \cdot S_{LT}^{L,j}$. 

pledged to creditors, which must be repaid using the non-pledged resources. Since riskless
debt is senior to equity, the intermediary must pledge part of the return from early projects to
its creditors, because the pool of risky projects cannot alone ensure that debt is repaid in full.

Using (21) we can then prove the following result:

**Proposition 3** If the share of early projects is $q_l$, the equilibrium at $t = 1$ is as follows:

a) if $\frac{I_{LT}}{S_L} > 1 + (\pi_d - \pi_r) + \frac{(1-q_l)}{q_l} E_\omega (\pi_\omega | \omega = l)$, then early intermediaries have a lot of
spare wealth at $t = 1$ and thus absorb all of the now risky debt, bidding up its market value to
their reservation value $V_1 = (1-q_l)E(\pi_\omega | \omega = l)A \cdot S_{LT}^{LJ}$;

b) if $\frac{I_{LT}}{S_L} \in [1 + (\pi_d - \pi_r) + \frac{(1-q_l)}{q_l} \pi_d, 1 + (\pi_d - \pi_r) + \frac{(1-q_l)}{q_l} \pi_d + E_\omega (\pi_\omega | \omega = l)]$, then early
intermediaries have a medium amount of spare wealth at $t = 1$. They still absorb all of the
now risky debt but now the market value of debt is $V_1 = q_l[A \cdot (I_{LT}^{LJ} - S_{LT}^{LJ}) - (\pi_d - \pi_r)A \cdot S_{LT}^{LJ}]$, which is lower than intermediaries’ reservation price;

c) if $\frac{I_{LT}}{S_L} < 1 + (\pi_d - \pi_r) + \frac{(1-q_l)}{q_l} \pi_d$, then early intermediaries have little spare wealth at $t = 1$. Now they cannot absorb all of the now risky debt, whose equilibrium price stays at
investors’ reservation value $V_1 = (1-q_l)\pi_rA \cdot S_{LT}^{LJ}$.

In cases a)-c) The ratio $\frac{I_{LT}}{S_L}$ and the difference $I_{LT}^{LJ} - S_{LT}^{LJ}$ fall with investors’ wealth $w$.

Proposition 3 shows that securitization creates financial fragility not only by exposing
unsuccessful intermediaries to unexpected aggregate shocks as we saw in Section 4.2, but
also by draining out market liquidity after the unexpected shock has occurred. When a large share of investment is securitized (i.e., $I_{LT}^{LT} - S_{LT}^{LT}$ is low), even intermediaries with “early” projects are illiquid when the unexpected shock occurs, because they had sold part of their successful projects to other intermediaries and they increased their leverage. This implies that, even if the un-securitized part of the portfolio is sufficiently large to allow “early” intermediaries to repay their own creditors, these intermediaries are unable to provide liquidity backstop to other creditors by purchasing the distressed debt claims of the “late” intermediaries. Once more, initial investor wealth is critical in creating financial fragility, for it is precisely when investors’ wealth is high that securitization and leverage are extensive, causing secondary debt markets to be fragile.\textsuperscript{12}

In Shleifer and Vishny (2010) and GSV (2011), market liquidity is scarce because the investment gains reaped by intermediaries induce them to commit all of their wealth at $t = 0$. In our model, in contrast, the insurance mechanism provided by securitization boosts fragility \textit{not only} by inducing intermediaries to commit their wealth ex-ante, but also and most distinctively by rendering the “spare wealth” conditions of different intermediaries highly correlated. In fact, the model in GSV can be viewed as a special case of this model in the range where securitization is full so that idiosyncratic risk is fully removed.

The case with partial securitization thus highlights the distinctive mechanism through which insurance creates fragility. In that case, it is still true that some unsuccessful intermediaries experience financial distress because, as in Shleifer-Vishny (2010) and GSV (2011), they have committed all of their wealth to investment. However, there are also other

\textsuperscript{12} Rather than re-trading risky debt in secondary debt markets, a better risk allocation at $t = 1$ could be achieved by additional financial innovation (tranching) at $t = 1$ whereby investors carve out the risky portion of debt repayment and sell it to intermediaries while keeping the safe portion for themselves.
successful intermediaries with unencumbered balance sheets willing and able to provide liquidity support. These intermediaries have also committed all of their wealth ex-ante, but the limited amount of securitization leaves them with some spare capacity to rescue the unsuccessful intermediaries thanks to the bonanza of early successful projects. There is market liquidity in the sense of Shleifer and Vishny (1992) and Brunnermeier and Pedersen (2009). The problem, however, is that when securitization is sufficiently extensive, the spare capacity of successful intermediaries is small, making them unable to provide significant backstop insurance to the unsuccessful intermediaries. By creating a correlation in the performance of different intermediaries through an endogenously-created network of relationships, securitization creates market illiquidity. This correlation can be naturally viewed as a source of the counter party risk created by the interlinkages typical of insurance arrangements, generating systemic risk in the sense of Giglio (2010).

5.2 Risky debt and risk premia

The previous analysis shows how trading and liquidity of riskless debt is shaped by securitization after the realization of neglected risks, but does not meaningfully explain changes in risk premia since risk averse investors do not hold risky securities. In our model, securitization and its link to financial fragility also have implications for risk premia.

To begin, note that the presence of “early” projects may allow intermediaries to expand debt capacity by issuing risky debt to investors. So far we have only considered the issuance of riskless debt claims pledging the lowest support of the risky pool \( \pi_d \cdot A \cdot S_{LT,j} \) (on top of the riskless return \( R_{LT,j} \)). However, the intermediary could issue a (risky) debt
security that pledges the entire cash flow from the pool, or equivalently it pledges the risky pool as collateral, effectively using securitization not only as pooling but also as a ring fencing device. Crucially, investors are willing to lend up to \( p_1 \cdot S_{LT,j}^{LT} \) for this security, where \( p_1 \) is the market value of risky collateralized debt at \( t = 1 \) in the event tree of Figure 5 that agents are thinking about. If investors expect to resell the pool at \( t = 1 \) at a price \( p_1 > \pi_d \cdot A \), pledging the entire pool as collateral allows intermediaries to increase the shadow value of securitization in terms of relaxing the riskless debt constraint (5), which becomes \( rD_j \leq R \cdot I_{H,j}^{LT} + p_1 \cdot S_{LT,j}^{LT} \). Debt capacity is indeed larger than in (20) precisely when \( p_1 > \pi_d \cdot A \). If instead investors expect a market price for risky collateral of \( p_1 = \pi_d \cdot A \), then posting risky collateral entails no expansion in debt capacity relative to purely riskless debt.

The possibility of market trading explains why it might indeed be the case that in equilibrium \( p_1 > \pi_d \cdot A \): intermediaries holding “early” projects are willing to pay more than \( \pi_d \cdot A \) for each unit of the pool because – being risk neutral – they also value the pool’s upside. Once again, the question is whether early intermediaries are sufficiently wealthy at \( t = 1 \) to sustain a high market price \( p_1 > \pi_d \cdot A \). In the remainder of this section, we sketch the analysis of an equilibrium where \( p_1 > \pi_d \cdot A \). The goal of our analysis here is not to fully characterize the equilibrium set, but to identify circumstances in which the very mechanism permitting the issuance of risky debt at \( t = 0 \) to investors – the expectation of ex-post market liquidity – evaporates when neglected risks materialize, creating fragility.

Consider an equilibrium in which the price at \( t = 1 \) is equal to intermediaries’ reservation value, namely \( p_1 = E_{\omega} (\pi_{\omega | \omega = l}) \cdot A \). To see under what condition this equilibrium is sustainable, note that along the expected path of events at \( t = 1 \) there is no default on debt, so
that the liquid resources of intermediaries are equal to \( q_h A (I^\text{LT}_{L,j} - S^\text{LT}_{L,j}) \). That is, intermediaries’ resources are equal to the non-securitized (and thus non-pledged) return of the early projects in \( h \). On the other hand, early intermediaries must absorb the market value of the totality of risky debt at their reservation price, which amounts to \( E_{\omega}(\pi_{\omega} | \omega = h) A S^\text{LT}_{L,j} \). The liquid resources of intermediaries are enough to absorb this amount when:

\[
\frac{I^\text{LT}_{L,j}}{S^\text{LT}_{L,j}} > 1 + \frac{E_{\omega}(\pi_{\omega} | \omega = h)}{q_h}.
\]  

(22)

When this equilibrium is sustained, i.e. (22) holds, intermediaries’ debt capacity is \( R \cdot I^\text{LT}_{L,j} + E_{\omega}(\pi_{\omega} | \omega = h) A S^\text{LT}_{L,j} \). For any value of \( S^\text{LT}_{L,j} \), this is above their debt capacity with riskless debt in Equation (20). Note that higher debt capacity does not boost aggregate borrowing because the aggregate resources available to intermediaries at \( t = 1 \) are fixed. The main feature of this arrangement is that the same amount of borrowing can be carried out using less securitization. Due to the presence of a liquid secondary market, each unit of securitization is more valuable to investors.

Since the left hand side \( I^\text{LT}_{L,j} / S^\text{LT}_{L,j} \) of Equation (22) falls with investors’ wealth \( w \), from subcase c) in Proposition 1 it follows that there exists a threshold \( \tilde{w} \) such that Equation (22) holds for \( w \in (R / E_{\omega}(\pi_{\omega} | \omega = h) A, \tilde{w}) \). Intuitively, for a secondary market to operate at \( t = 1 \), investors’ wealth must be sufficiently large \([w > R / E_{\omega}(\pi_{\omega} | \omega = h) A]\) that some assets are securitized. On the other hand, if investor wealth is too large, securitization is so extensive that early intermediaries are illiquid even in good times, making it impossible for them to buy all risky claims at their reservation price. Hence, we must have \( w < \tilde{w} \).
In terms of the $t = 0$ equilibrium, note that when $w \in (R/E_{\omega}(\pi_{\omega}) \cdot A, \tilde{w})$ securitization is partial, otherwise (22) would not hold, and thus $r = E_{\omega}(\pi_{\omega}\mid \omega = h)A$, just as in subcase c) of Proposition 1. In this equilibrium, at $t = 0$ risk averse investors buy risky debt at the equilibrium interest rate valuing the underlying risky collateral at $E_{\omega}(\pi_{\omega}\mid \omega = h)A$, which is precisely the intermediaries’ reservation price. In this precise sense, at $t = 0$ the risk premium on risky debt is equal to zero. Intuitively, even if investors dislike risk, they value collateral at its risk neutral value because they believe that tomorrow they can sell their debt in a liquid market dominated by risk neutral investors.\textsuperscript{13}

Once more, however, this arrangement is very sensitive to neglected risk. When at $t = 1$ market participants observe a low share of “early” projects $q_l$, they immediately realize that, in the most optimistic scenario, they are only able to sell at the average price $E_{\omega}(\pi_{\omega}\mid \omega = l)A$, which is less than what they expected to obtain at $t = 0$. The unexpected bad state reduces intermediaries’ valuation at $t = 1$, exposing investors to resale risk. Most important, however, even if intermediaries’ valuation does not change much, in the sense that $E_{\omega}(\pi_{\omega}\mid \omega = l) \approx E_{\omega}(\pi_{\omega}\mid \omega = h)$, investors are also exposed to the possibility that a bad realization of a neglected risk may cause liquidity at $t = 1$ to evaporate. This effect can be so strong as to drive the price of risky debt at $t = 1$ down to investors’ ex-post valuation, which has become equal to $\pi_r \cdot A$. In this case, the risk premium jumps from zero at $t = 0$ to $[E_{\omega}(\pi_{\omega}\mid \omega = l) - \pi_r]A$ at $t = 1$.

We now identify the conditions leading to this case, which illustrates in the starkest manner the mechanism for fragility under risky debt. This case arises when $q_rA(I_{L_j}^{LT} - S_{L_j}^{LT})$,

\textsuperscript{13} Although this mechanism works though the trading of long term debt, the same intuition can be developed in the context of riskless debt in terms of the expectation of debt rollover at $t = 1$. Another possibility to implement the same equilibrium is for investors rather than intermediaries to buy the securitized pools at the outset.
the liquid resources of intermediaries at \( t = 1 \), are insufficient to absorb all risky debt at investors’ reservation price. This occurs provided:

\[
\frac{I_L^{LT}}{S_L^{LT}} < 1 + \frac{\pi_r}{q_i},
\]

which holds when the non-securitized portion of the investment by successful intermediaries is sufficiently small. Conditions (22) and (23) are mutually consistent provided:

\[
\frac{q_i}{q_h} < \frac{\pi_r}{E \sigma \left( \pi_r | q_h \right)}.
\]

When (24) holds, there is a range of investors’ wealth levels for which intermediaries expand debt capacity by selling risky debt to investors. This debt is sold without a risk premium at \( t = 0 \), but its risk premium becomes very large when neglected risks materialize.

Here the novel aspect causing both the boom and bust in the value of debt and the fluctuation in risk premia is securitization itself. In good times, securitization reduces risk premia by creating a relatively safe and liquid form of collateral. After all, the investor thinks, if the intermediary is hit by an adverse idiosyncratic shock, he can always sell its debt in the market and reduce his downside risk. This effect sustains ex-ante leverage. In bad times, however, securitization creates a strong correlation in the returns of intermediaries, which renders secondary markets very illiquid after bad aggregate news. This drives risk premia up as neglected risks materialize. The problem here is that the local thinking investor neglects the possibility that the intermediary whose debt he owns goes under precisely when many other debtors go under as well. In these neglected states, the very securitization that had created the illusion of safety causes liquidity to collapse. As a consequence, the risk-averse investor is stuck with risky debt, which causes the risk premium to rise.
6. Discussion

In this section, we compare the three broad theories of shadow banking and securitization, and consider their implications for the financial crisis. Early research on securitization focuses on the roles of pooling and tranching of risks to overcome adverse selection problems. The foundational papers include Gorton and Pennachi (1990), De Marzo and Duffie (1999), De Marzo (2005), and Dang, Gorton, and Holmstrom (2009). According to this “adverse selection” view of securitization, the essential feature of safe securities is that all investors are symmetrically informed (or symmetrically ignorant) about their payoffs, and therefore can buy without fear that the seller knows more about them do. The informational symmetry among investors creates a liquid market for safe debt.

The second theory, which we refer to as the “regulatory arbitrage” view, sees securitization principally as a strategy of avoiding bank capital regulations. Some of the key papers include Calomiris and Mason (2003), Acharya and Richardson, eds. (2009), and Acharya, Schnabl, and Suarez (2011). According to this view, banks pursued securitization through off-balance-sheet Special Investment Vehicles (SIV’s) to get around capital requirements. A second aspect of regulatory arbitrage is bond-rating manipulation through financial engineering (Ashcraft et al 2010, Benmelech and Duglosz 2009, Stanton and Wallace 2011). By transforming a fraction of assets held on their balance sheets into highly rated securities, banks were able to sustain higher leverage and still comply with risk-weighted capital requirements. The regulatory arbitrage view is often combined with a separate idea of “too big to fail,” namely that banks were willing to provide liquidity guarantees to SIV’s and otherwise retain risks because they counted on a government bailout if things went badly (Acharya and Richardson eds. 2009).
The third view, which we have developed in this paper, is that securitization meets the demand for safe debt by pooling and tranching cash flows so as to reduce the perceived risk of the securities thus manufactured. In some respects, this “safe debt” view is the most neoclassical of the three theories since, under rational expectations, ours is simply a theory of efficient risk allocation between the risk-averse investors and risk neutral intermediaries.

All three views deliver some of the main facts about the shadow banking system. First, all three theories start with substantial demand for safe debt, for regulatory, liquidity, or risk aversion reasons. Second, they all see securitization as a financial innovation that meets this demand by pooling and tranching cash flows. Under the adverse selection view, securitization eliminates adverse selection; under the other two views, it merely reallocates risks between those willing and unwilling to bear them. Indeed, under all three views banks become highly leveraged in the process of securitization; after all, the product they create for the market, namely safe debt, is the liability side of their balance sheets, with risky loans as inputs in the manufacturing process. Third, all three theories explain why banks retain risk. In the adverse selection view, banks retain risks because the securities they sell must be safe enough to avoid triggering investment in information. In the regulatory arbitrage view, banks retain tail risks because they count on a bailout. In the safe debt view, banks are the efficient bearers of risk, and hence retain it efficiently (under rational expectations).

All three views also lead to a theory of how a bad shock precipitates a financial crisis. Under the adverse selection view, a piece of bad news raises the probability of default on safe debt enough to trigger investment in information by market participants. As soon as they begin investing, market participants realize that they could be less informed than their trading counterparts, and become reluctant to trade. Liquidity evaporates and markets crash.
Indeed, even relatively minor pieces of bad news, in so far as they precipitate a quest for information, can unravel markets.

Under the regulatory arbitrage view, a piece of bad news either about cash flows or about the government's commitment to bank rescues, or about both, would destabilize a highly leveraged bank. There could be a run on the bank, or a refusal of the lenders – the buyers of the short term securities the bank issues – to continue buying them. When several banks experience this shock, or when banks are interdependent, the financial system can collapse. It is precisely because banks are able to evade capital requirements and lever up so much that they are so vulnerable to shocks.

Under our safe debt view (with neglected risk), “safe” debt is over-issued against securitized pools. As these pools are recognized to be riskier than initially believed, intermediaries experience losses and risk-averse lenders become exposed to default risk, precipitating fragility and illiquidity.

The three theories are not mutually exclusive. It is likely that in the financial crisis of 2007-2009, all played a role. Nonetheless, we next address some of the objections to, or weaknesses of, all three theories, in part to explain why we think ours is needed.

The regulatory arbitrage theory combined with “too big to fail” makes many compelling points, but leaves some questions open. First, many institutions not subject to risk-weighted capital requirements, including investment banks and hedge funds, were major holders of securitized assets on a highly leveraged basis (He, Kang and Krishnamurthy, 2010). It appears that these institutions pursued the same carry trade as the regulated banks, using short term borrowing to finance holdings of securitized assets. In contrast to these less
regulated institutions, many large banks that were subject to capital requirements did not participate extensively in securitization activities (Erel, Nadauld, and Stulz, 2011).

A second issue is the dearth of evidence that distorted incentives of decision makers played a role in explaining which institutions took the biggest risks and got into the most trouble. Using data on CEO compensation, Fahlenbrach and Stulz (2011) and Erel, Nadauld, and Stulz (2011) do not find that those CEOs with significant equity stakes, who presumably had the most to lose in a crisis, acted any more conservatively before the crisis than the others. Calomiris and Mason (2003) study credit card securitizations. While finding some evidence consistent with regulatory arbitrage, they also find that banks set their capital as a function of market perceptions of risk rather than to maximize the implicit subsidy from a government bailout.

These are not, however, our main concerns. The most troubling question about the regulatory arbitrage view is why, prior to the crisis, there was so little indication in the markets of elevated risks resulting from high leverage, ratings inflation, and questionable financial engineering. A complete theory of the crisis should account not only for its spread through the financial system, but also for the dramatic failure of markets to anticipate it.

Under the regulatory arbitrage view, banks and other market participants were well aware of the increased risks being taken prior to the crisis, but were counting on a bailout. But wouldn’t this increased risk show up somewhere in bond spreads or CDS prices if everyone was aware of it? Perhaps one could make a case that for the debt of very large banks, a bailout was so certain that default spreads should not have even reflected the increased risks being taken. But belief in the absolute certainty of a government bailout in which all debt holders come out whole seems downright implausible for investment banks
(especially with the benefit of hindsight). Yet there were no warning signals emanating from financial markets prior to the middle of 2007. Similarly, if ratings were being inflated through questionable financial engineering of securities such as MBS and CDOs, the spreads on such securities should have fully reflected the increased risk of default, but apparently they did not (Ashcraft et al 2010, Coval et al 2009a,b, Jarrow et al 2007). Even if many of the holders of these securities were large banks counting on bailouts, the individual securities themselves were definitely not immune to default.

The adverse selection view faces similar problems. For example, it requires some subtle maneuvers to explain why markets collapsed in the fall of 2008, and not in the summer or fall of 2007. After all, a lot of bad news about housing came into the market in mid 2007, and led to several bankruptcies of financial institutions, the collapse of the ABCP market, and substantial elevation of risk premia. Yet, according to the adverse selection model, these events were not sufficient to trigger information acquisition about MBS and CDO’s, which would of course have raised the spectre of adverse selection. It is possible that in 2007 the benefit of education about this debt, even to market participants, was low enough for them to choose ignorance. However, warning signs should have caused the prices of MBS and CDOs to incorporate the risk of future investigation and thus an unraveling of these markets.

The reason that we feel our story is necessary, then, is precisely to come to grips with the fundamental fact that financial markets did not understand the risks of MBS and CDOs even after some of the bad news starting filtering in. To account for this fact, both the regulatory arbitrage and the adverse selection views require the presence of neglected risks. But once the neglect of risks is introduced, we show that one can obtain a theory of the crisis without additional frictions such as distorted incentives or adverse selection. The safe debt
view provides a parsimonious account of both the ex-ante and the ex-post aspects of the crisis by relying only on market participants’ neglect of low probability downside risks.

Yet our story raises several questions also, and we briefly consider those as well. To begin, one can argue that one does not need securitization for banks to issue safe debt. After all, the issuing banks were some of the most diversified institutions in the world, and could have issued commercial paper and repo backed by their own cash flows to meet the demand. Why, then, securitization? Banks indeed issued a large volume of safe debt, including commercial paper and repo, to meet the growing demand, and had their own diversified loan portfolios to enable them to do it. In our model, however, there is only a limited supply of bank’s own cash flows that can sustain issuance of riskless debt. When investors wanted more, the banks could not generate enough safe cash flows of their own. They then engaged in a variety of practices, from diversification, to liquidity guarantees, to pledging collateral directly, to ensure the safety of the additional debt they issued. The mechanics of securitization is strongly supportive of the view that it was a market response to rapidly growing demand, met by intermediaries best positioned to satisfy it.

Perhaps the more radical objection to our model is that neither securitization nor the neglect of risk is necessary to explain this crisis or crises more generally. Securitization is not necessary because banks often take enormous risks without securitization, perhaps for incentive reasons (Rajan 2006), and then get into trouble. After all, while most historical episodes of financial crises are associated with heavy lending by banks to activities that end up defaulting, such as real estate, securitization is a recent innovation. Neglect of risk is not necessary because what we might have seen in 2008 is a rare disaster (Barro 2006, Gabbaix 2011), or a perfect storm.
Note first that our argument is not that securitization is always necessary for a crisis, but rather than securitization was an essential part of this crisis. All three theories we have discussed share this element and seek to understand the relationship between securitization and financial fragility. It is not surprising in this regard that the crisis started in the US and the UK, the two countries not with the greatest housing bubbles (those were Ireland and Spain), but with the greatest reliance on securitization. Indeed, we argued throughout the paper that the advantage of our model is that it can explain both securitization and financial fragility in the same framework that appears to deliver many additional empirically documented features of the most recent episode. One of the critical functions of financial innovation is precisely to look different so as to alleviate the concerns about risk that investors have from the past experiences they remember. Securitization did exactly that.

With respect to the claim that one can get a crisis under rational expectations, we note two points. First, it is not our claim that all tail risks are always neglected. In fact, many catastrophic events such as sovereign defaults often loom large in investors’ minds, and our theory does not apply to such risks. But second, to say that some rare disasters are contemplated by markets is not to say that all of them are. We have tried to lay out throughout the paper the direct evidence that, in the crisis of 2007-2009, critical risks were neglected. Even as late as mid-2007, there is no evidence in CDO, MBS, or CDS prices that investors suspect a likely catastrophe. As Coval et al. (2009a, b) have pointed out, the prices of bonds in 2007 reflect trivial risk premia, not vast risks of default. Direct evidence on credit ratings, models used by rating agencies, on forecasts about housing prices, on internal communications inside financial institutions, all point to a massive failure to consider the possibility of a disaster, let alone predict it. A model of an unanticipated rare disaster can of
course “explain” the crisis, but it does not explain much else in the data. It is precisely the
direct evidence that the disaster that occurred in 2007-2009 was unanticipated, combined
with direct evidence on the key role of securitization in capitalizing on this expectational
error, that necessitate our model.

Our view of the shadow banking system has several empirical implications that may
help to distinguish it from the other theories discussed here. First, our view sees financial
crises as manmade disasters which therefore occur more frequently than might be expected in
a neoclassical framework, where market participants (lenders under regulatory arbitrage,
borrowers and lenders under adverse selection) act so as to minimize the risks of default and
bankruptcy. Our model also has the implication that a post-mortem analysis of market data
shows few signs that market participants were aware of the risks being taken. Second, when
key decision makers do not appreciate the risks they take, looking at management incentives
would not predict very well which institutions get into trouble. It is difficult to argue that top
executives at Lehman and Bear Stearns had incentives to take big risks because they faced
little downside. Third, greater securitization in our model is associated with a greater
likelihood of financial fragility. Witness the speed with which the crisis unfolded in the US
and the UK versus in the rest of Europe. Finally, because investors may extrapolate past
returns and become wrongly convinced of the safety of certain assets, future crises are more
likely to be associated with assets that have shown little downside risk in the recent past.

7. Conclusion

We presented a new model of shadow banking that describes securitization without
any risk transfer outside the core banks. Securitization allows banks to diversify
idiosyncratic risk while concentrating their exposure to systematic risk. This process enables them to expand their balance sheets by essentially funding carry trades with riskless debt. When all risks are recognized ex ante, this market efficiently allocates them to risk-neutral financial intermediaries, and expands opportunities for insurance and intertemporal trade. This view of securitization under rational expectations accounts for many empirical phenomena, including the role of the demand for safe debt in driving securitization, the comovement of bank assets and leverage, and the rising interdependence of banks as a byproduct of securitization. This view also suggest that the shadow banking system becomes extremely fragile when tail risks are neglected. The trouble is not the realization of neglected risks per se, but the increase in the total amount of risk-taking that securitization facilitates. Securitization magnifies exposure to unrecognized aggregate risks through contracts between intermediaries that, absent neglect, would improve welfare.

One might ask how this mechanism differs from the more basic proposition that banks often finance risky projects, such as mortgages, and occasionally face huge losses when such financing turns sour. What is new about securitization is that it enables intermediaries to access enormous pools of short-term capital seeking riskless returns even without government deposit guarantees. By identifying activities in which investors misperceive risks, perhaps because these investors pay too much attention to recent history, financial intermediaries through securitization can finance a lot more risk than they could without it. The cost, of course, is that they bear the residual risk themselves. It is precisely the process of risk control through diversification and securitization that leads to the exposure of all intermediaries to common risks, and generates aggregate instability in excess of what would occur if each bank speculated on its own. Moreover, because the availability of short-term
finance is tied directly to the perceived safety of publicly traded securities held by many banks, bank runs quickly turn system-wide. Insurance contracts intended to be risk-reducing end up being risk-enhancing, especially from a systemic point of view.

The risks neglected by market participants tend to be subtle and constantly evolving. For this reason, it is optimistic to expect market regulators to identify these risks when investors and even intermediaries fail to do so. Still, some policy interventions might make the system more stable. The most obvious, if crude, instrument is capital requirements, which can successfully reduce the ability of intermediaries to expand their risky activities even when risks are neglected. Our model suggests that it is better to control overall bank leverage, to the extent this is possible, than to rely on risk-weighted capital requirements, since ratings are vulnerable to the neglect of risks. The failure of rating agencies during the crisis is eloquent testimony to this effect. Alternatively, regulators might raise a red flag when they see increasing exposure of intermediaries to a particular sector, such as real estate, especially when accompanied by securitization and collateralized borrowing. Regulators might also be wary of financial innovations such as prime money market funds whose appeal consists of offering higher returns with allegedly no risk. Knowledge of which risks are neglected is not essential for recognizing the signs of such neglect in the financial system.
8. Proofs

At $t = 0$, a generic intermediary $j$ solves the optimization problem:

$$
\max_{(D, I_H, T_H, S_H, I_L, T_L)} \left[ R (I_H + T_H - S_H) + p_H(S_H - T_H) \right] + \\
\left( E_\omega(\pi_\omega) \cdot A \cdot (I_L - S_L) + E_\omega(\pi_\omega) \cdot A \cdot T_L + p_L(S_L - T_L) \right] -
$$

$$
+ D - I_H - I_L + w_{int} - rD,
$$

(A.1)

Subject to:

$$
w_{int} + D - I_H - I_L - p_H(T_H - S_H) - p_L(T_L - S_L) \geq 0, \quad (A.2)
$$

$$
R (I_H + T_H - S_H) + \pi_r \cdot A \cdot T_L - rD \geq 0, \quad (A.3)
$$

$$
I_H - S_H \geq 0, \quad (A.4)
$$

$$
I_L - S_L \geq 0, \quad (A.5)
$$

where we drop subscript $j$ for ease of notation. Denote by $\mu$ the multiplier attached to the resource constraint (A.2), by $\gamma$ the multiplier attached to the riskless debt constraint (A.3), by $\theta_H$ and $\theta_L$ the multipliers attached to the securitization constraints (A.4) and (A.5), respectively. We also denote by $\nu$ the multiplier attached to the aggregate constraint $1 - \int j I_H \, dj \geq 0$, which must be considered by the intermediary when investing the last unit of $H$.

The first derivatives of the Lagrangian with respect to the choice variables are then equal to:

$$
I_H : \quad R - 1 - \mu + \gamma R - \nu + \theta_H, \quad (A.6)
$$

$$
T_H : \quad R - p_H - \mu p_H + \gamma R, \quad (A.7)
$$

$$
S_H : \quad -R + p_H + \mu p_H - \gamma R - \theta_H, \quad (A.8)
$$

$$
D : \quad 1 - r + \mu - \gamma r, \quad (A.9)
$$

$$
I_L : \quad E_\omega(\pi_\omega) \cdot A - 1 - \mu + \theta_L, \quad (A.10)
$$

$$
T_L : \quad E_\omega(\pi_\omega) \cdot A - p_L - \mu p_L + \gamma \pi_r \cdot A, \quad (A.11)
$$
\[ S_L : \quad - \mathbb{E}_w(\pi_w) \cdot A + p_L + \mu p_L - \theta_L. \] (A.12)

Together with investor optimization, (A.2) to (A.12) yield the model’s equilibrium. The conditions determining investors’ optimal consumption-saving problem are easy. Given investors’ preferences [Equation (1)], the marginal benefit for an investor \( i \) of lending \( D_i \), purchasing \( T_{H,i} \) riskless projects and \( T_{L,i} \) pools of risky projects are respectively equal to:

\[ D_i : \quad -1 + r, \] (A.13)
\[ T_{H,i} : \quad -p_H + R, \] (A.14)
\[ T_{L,i} : \quad -p_L + \pi \cdot A, \] (A.15)

Consider now what (A.2) to (A.15) imply for the model’s equilibrium. First, note that (A.9) and (A.13) imply that in equilibrium \( r \geq 1 \), otherwise no investor is willing to lend. Thus, the only feasible lending pattern is for investors to lend resources to intermediaries who have productive projects and can therefore afford to pay \( r \geq 1 \).

**Proof of Lemma 1** Consider first how intermediaries optimally finance a riskless investment \( I_H > 0 \) using borrowing and securitization. With respect to capital suppliers, investors (or lending intermediaries) prefer securitization \( T_{H,i} \) when it yields a higher return than bonds \( D_i \), i.e. when \( R/p_H > r \). The reverse occurs when \( R/p_H < r \). When \( R/p_H = r \), capital suppliers are indifferent. On the demand side, if \( R/p_H > r \), then by (A.8) and (A.9) intermediaries prefer debt \( D_j \) to securitization \( S_{H,j} \), if \( R/p_H < r \), the reverse is true. In equilibrium it must be that:

\[ R/p_H = r, \] (A.16)

namely bonds and securitization should yield the same return. From Equations (A.8) and (A.9) one can also see that when (A.16) holds, the shadow cost of securitizing riskless
projects is weakly higher than that of issuing bonds because $\theta_H \geq 0$. We thus focus on equilibria where riskless projects are not securitized, namely $S_H = T_H = 0$ (and $\theta_H = 0$).

Next, consider the securitization of risky projects. Suppose that intermediaries engage in risky investment $I_L > 0$ and securitize $S_L > 0$ of it. Investors buy securitized claims if they yield them more than riskless bonds, i.e. if $\pi_A / p_L \geq r = R / p_H$. By plugging this condition into Equation (A.11), one finds that if investors demand securitized risky claims $T_{L,j}$, then intermediaries demand an infinite amount of them, which cannot occur in equilibrium. Formally, if $\pi_A / p_L \geq r = R / p_H$ the benefit of increasing $T_{L,j}$ is positive, because it is larger than that of increasing $T_{H,j}$ (and the latter benefit must be equal to zero, for riskless projects are not securitized). But then, in equilibrium it must be that $\pi_A / p_L < r$ and the available securitized risky claims are traded among intermediaries, namely $T_{L,j} = S_{L,j}$. Equations (A.11) and (A.12) show that starting from a no securitization situation (i.e. $\theta_L = 0$), purchasing securitized projects is strictly beneficial (and so $T_{L,j} = S_{L,j} > 0$) if the debt constraint (A.3) is binding, namely when $\gamma > 0$.

**Proof of Proposition 1** Since $R \geq E_\omega(\pi_\omega) \cdot A$, investment in $H$ is preferred to that in $L$ if $H$ is available, i.e. when $\nu = 0$ in (A.6). In this case, the marginal benefit of $I_H$ in (A.6) is larger than that of $I_L$ in (A.10) provided:

$$R - E_\omega(\pi_\omega) \cdot A \geq \theta_L - \theta_H - \gamma R. \tag{A.17}$$

Since riskless projects are not securitized ($\theta_H = 0$), Equation (A.17) is satisfied if $\gamma R \geq \theta_L$, i.e. if the riskless project boosts leverage more than securitization. This is true if securitization does not occur (i.e. $\theta_L = 0$) but also if it does. In the latter case, the fact that risky projects are only traded among intermediaries, i.e. $T_{L,j} = S_{L,j}$, calls for (A.11) to be equal to minus (A.12).
This requires $γπA = θ_L$ and thus implies $γR ≥ θ_L$. Hence, intermediaries invest in $H$ until investment in such activity is equal to 1. Beyond that limit, intermediaries invest also in $L$.

Consider the equilibrium when $\omega = 0$ and all wealth goes to finance $H$ and financial constraints are not binding ($γ = 0$) since $H$ is self-financing. By plugging $r = 1 + \mu$ from (A.9) into (A.6), we find that $r = R$. Thus, equilibrium prices are $(r = R, p_H = 1, p_L)$ where $πrA/R ≥ p_L ≤ 1$ and quantities are $(D = w, I_H = \omega + w, I_L = 0, S_H = S_L = T_H = T_L = 0)$. Investors lend their wealth at $t = 0$ by purchasing riskless bonds that promise $R$ at $t = 2$. No lending or trading occurs at $t = 1$, because after $ω$ is learned investors and intermediaries have the same preferences and value all assets equally. The consumption patterns of intermediaries is $C_0 = C_1 = 0, C_2 = Rw$, that of investors is $C_0 = 0, C_1 = 0, C_2 = Rw$.

Consider the equilibrium when $\omega > 1$. Now activity $H$ is exhausted, i.e. $ν > 0$. There are two cases to consider, depending on whether $E_ω(πω)A$ is higher or lower than one.

1) If $E_ω(πω)A ≤ 1$, then intermediaries do not invest in $L$. To see this: by Equation (A.10), $I_L > 0$ can only be optimal if securitization is valuable, i.e. if $θ_L > 0$. For this to be the case, the resale price of the project must be higher than the investment cost, i.e. $p_L ≥ 1$. No intermediary is willing to buy at $p_L ≥ 1$, as the project yields less than 1. Thus, if $E_ω(πω)A < 1$ we have $S_L = T_L = I_L = 0$. In this equilibrium it must be that $r = 1$. If $r > 1$ investors lend all of their wealth $w$ and intermediaries’ budget constraint becomes slack ($μ = 0$) because $\omega + w > I_H = 1$. But then equation (A.9) implies $γ < 0$, which is impossible. Thus, in equilibrium $r = 1$ and intermediaries’ debt can take any value $D ∈ (1 − w, \min(w, R))$ by the riskless debt constraint (A.3). For a given $D$, the consumption of intermediaries is $C_0 = w + D − 1, C_1 = 0, C_2 = R − D$, that of investors is $C_0 = w − D, C_1 = 0, C_2 = D$. Once more, there is neither trading nor lending at $t = 1$.  

59
2) If $E_\omega(\pi_\omega)A > 1$, intermediaries wish to invest in $L$. There are three cases.

2.1) If $w$ is sufficiently low, intermediaries finance $L$ with a slack debt constraint, i.e. $\gamma = 0$, and without securitization, so that $\theta_L = 0$ and $S_L = T_L = 0$. In this case, (A.9) and (A.10) imply $r = E_\omega(\pi_\omega)A > 1$. As a consequence, investors lend all of their wealth and $D = w$ and $I_L = w + w_{int} - 1$. The riskless debt constraint (A.3) is slack for $R \geq E_\omega(\pi_\omega)A \cdot w$, so this allocation is an equilibrium for $w \in (1-w_{int}, R/E_\omega(\pi_\omega)A]$.

2.2) If $w$ increases further, intermediaries start to securitize risky projects, so that $S_L = T_L > 0$, but not yet to the full amount of investment, i.e. $\theta_L = 0$. In this case because of $\theta_L = \gamma \pi_r A$ by (A.11) and (A.12), the debt constraint holds with equality even though there is no shadow cost (i.e. $\gamma = 0$), so that it is still the case that $r = E_\omega(\pi_\omega)A > 1$ by (A.9) and (A.10). Investors lend $w$ to intermediaries and the equilibrium level of securitization is determined along the debt constraint (A.3) as follows:

$$E_\omega(\pi_\omega)A \cdot w = R + \pi_r A \cdot S_L,$$

(A.18)

which implicitly identifies the level of securitization $S_L$ increasing in $w$. This allocation constitutes an equilibrium (thus satisfying $\theta_L = 0$) only if $S_L < I_L = w + w_{int} - 1$, which corresponds to the condition:

$$w \leq w^* \equiv \frac{R \cdot A + \pi_r (w_{int} - 1)}{E_\omega(\pi_\omega) - \pi_r}.$$

(A.19)

Condition (A.19) implies that this configuration is an equilibrium for $w \in (R/E_\omega(\pi_\omega)A, w^*)$.

2.3) If $w$ increases beyond $w^*$, securitization hits the constraint $S_L = I_L$, i.e. $\theta_L > 0$. In this case the debt constraint is binding, i.e. $\gamma > 0$, and the interest rate drops to $r < E_\omega(\pi_\omega)A$ by (A.9) and (A.10). As long as $r \geq 1$, investors lend $w$ to intermediaries and the equilibrium interest rate is implicitly determined along the debt constraint (A.3) as follows:
\[ r \cdot w = R + \pi_r A (w + w_{int} - 1), \] (A.20)

which implicitly identifies a function \( r(w) \) that monotonically decreases in \( w \) and approaches \( r = \pi_r A \) as \( w \rightarrow +\infty \). Due to A.1, since \( \pi_r A < 1 \) there is a threshold level of wealth \( w^{**} \) such that \( r(w^{**}) = 1 \). Obviously then, intermediaries cannot absorb investors’ wealth beyond \( w^{**} \).

Once more, in all equilibria 2.1) – 2.3) nothing happens to lending and trading at \( t = 1 \). It is straightforward to derive agents’ consumption patterns.

**Proof of Proposition 2** The construction of the equilibrium is identical to the one discussed in the proof of proposition 1, except the now we replace \( \pi_r \) with \( \pi_d \) in the debt constraint (A.3) and investors’ return \( E_\omega(\pi_\omega) \) on \( T_{Lj} \) in (A.15) with \( E^{LT}_\omega (\pi_\omega) \) in the intermediary’s objective. Compare now the extent of securitization under local thinking and under rational expectations. Clearly, we have that \( S^{LT}_L > S_L \) for all \( w \) provided \( w^{**LT} < w^* \) because in this case local thinking intermediaries max out securitization for lower values of \( w \). Since at these values the level of investment is the same under LT and RE, securitization is higher in the former regime. After some algebra, one can find that \( w^{**LT} < w^* \) for all \( w_{int} \leq 1 \) provided:

\[
E^{LT}_\omega (\pi_\omega) - \pi_d > E_\omega (\pi_\omega) - \pi_r \iff \phi_g \phi_r (\pi_g - \pi_d) > (\phi_g + \phi_d)^2 (\pi_d - \pi_r),
\]

which is fulfilled provided the expectational error \( (\pi_d - \pi_r) \) is small. If the condition above is not met, it might be that \( w^{**LT} > w^* \). In such a case, for \( w \) on the left neighbourhood of \( R/E_\omega(\pi_\omega) \mid t = 0 \cdot A \) securitization is higher under LT (there is no securitization under RE yet). For \( w \) above \( w^{**} \), investment and securitization are also higher under LT. However for \( w \) intermediate securitization might be higher under RE.

61
Consider now the interest rate. When $w^{*LT} > w^*$ it is obvious that $r^{LT} \geq r$, but even if $w^{*LT} < w^*$ it is easy to see that $r^{LT} > r$. To see that, consider the interest rate prevailing under local thinking when $w = w^*$. Indeed, if $r^{LT} < r$ at any wealth level, then it must be that $r^{LT} < r$ also at $w = w^*$. It is easy to see that the fact that $(\pi_d - \pi_r) > 0$ implies that at $w = w^*$ we always have $r^{LT} > r$ confirming that the interest rate is weakly higher under local thinking.

Finally, consider leverage $D$. It is immediate to see that until wealth level $w^{**}$ leverage and investment are the same under LT and RE (i.e. $D = w$), but that for $w > w^{**}$ leverage and investment are strictly higher under LT, confirming that $D^{LT} \geq D$. Indeed, since $\pi_rA < 1$ we have that $w^{**} = [R - \pi_rA(1-w_{int})]/(1 - \pi_rA)$, which increases in $\pi_r$, implying that $w^{**} < w^{*LT}$.

**Proof of Proposition 3** We again focus on the case where $E_{w_0}(\pi_{w_0} | t = 0) \cdot A > 1$. From the proof of Proposition 1 we know that for $w \leq R/ E_{w_0}(\pi_{w_0} | t = 0) \cdot A$ there is no securitization and thus fragility does not arise [i.e. we are in cases a) and b)]. For $w \geq w^{*LT} = \frac{R/A + \pi_d (w_{int} - 1)}{E_{w_0}(\pi_{w_0} | t = 0) - \pi_d}$ we know that securitization is maximal, namely $I^{LT}_{H} = S^{LT}_{L,j}$. We are in case d), in which intermediaries have no spare resources at $t = 1$. In this case, intermediaries cannot buy back any of the debt claims from investors, and in equilibrium $V_1 = (1-q_l)\pi_rA \cdot S^{LT}_{L,j}$, which is investors’ reservation value. Plugging equilibrium values, we find that in this case:

$$V_1 = (1-q_l)\pi_rA \cdot (w_{int} + \min(w, w^{**LT}) - 1)$$

where $w^{**LT} = [R - \pi_d A(1-w_{int})]/(1 - \pi_d A)$. 

62
The most interesting case arises when \( w \) lies in \( (R/E_{\omega}(\pi_{\omega} t = 0), w^{*LT}) \). In this range, securitization is pinned down by condition \( E_{\omega}(\pi_{\omega} t = 0)A \cdot w = R + \pi_{d}A \cdot S_{L,j}^{LT} \), which implies:

\[
I_{L,j}^{LT} - S_{L,j}^{LT} = \frac{R/A}{\pi_{d}} - (1 - w_{int}) - (\varphi_{g} + \varphi) \left( \frac{\pi_{g}}{\pi_{r}} - 1 \right) w,
\]

which decreases in investors’ wealth, attaining a maximum value in the relevant wealth interval of \( I_{L,j}^{LT} = w_{int} + R/E_{\omega}(\pi_{\omega} t = 0) - 1 \) and reaching a minimum of 0 at \( w^{*LT} \).

Since the wealth available to intermediaries at any \( w \) is equal to \( q_{l}[A \cdot (I_{L,j}^{LT} - S_{L,j}^{LT}) - (\pi_{d} - \pi_{r})A \cdot S_{L,j}^{LT}] \), the equilibrium value of risky debt \( V_{1} \) as a function of \( (I_{L,j}^{LT} - S_{L,j}^{LT}) \) can be in one of the following configurations. If \( q_{l}[A \cdot (I_{L,j}^{LT} - S_{L,j}^{LT}) - (\pi_{d} - \pi_{r})A \cdot S_{L,j}^{LT}] > (1 - q_{l})E(\pi_{\omega}[q_{l}])A \cdot S_{L,j}^{LT} \), then the market value of risky debt is equal to intermediaries’ reservation value \( (1 - q_{l})E(\pi_{\omega}[q_{l}])A \cdot S_{L,j}^{LT} \). If \( q_{l}[A \cdot (I_{L,j}^{LT} - S_{L,j}^{LT}) - (\pi_{d} - \pi_{r})A \cdot S_{L,j}^{LT}] < (1 - q_{l})\pi_{r}A \cdot S_{L,j}^{LT} \), then the market value of risky debt is equal to investors’ reservation value. Otherwise, the market value of risky debt is equal to intermediaries’ wealth \( q_{l}[A \cdot (I_{L,j}^{LT} - S_{L,j}^{LT}) + (\pi_{d} - \pi_{r})A \cdot S_{L,j}^{LT}] \).
